The relationship between *H. pylori* and GERD has been of interest for decades. The observation that gastric mucosal atrophy was less frequent in patients with reflux esophagitis was made well before the *H. pylori* era. Evolutionary hypotheses assume, and the majority of available epidemiologic data show, that the decline of *H. pylori* infection is one of the reasons behind the increasing incidence of GERD-related diseases including esophageal and cardia adenocarcinoma in the Western world. This inverse relationship is strongest between *H. pylori* and esophageal adenocarcinoma, although significant evidence relates *H. pylori* and the development of Barrett esophagus and GERD. Over the period from 1970 to 1995, the incidence of both duodenal ulcer, compared to erosive esophagitis, and distal gastric cancer, compared to gastric cardia cancer, displays strikingly opposing time trends. It has been postulated that *H. pylori*-induced chronic corpus gastritis may protect against the development of GERD and its malignant transformation. A detailed report by Labenz et al.⁶⁸ in 1997 provided some of the first evidence in support of this theory. In a case-control study of 460 duodenal ulcer patients, new-onset GERD symptoms were significantly higher in patients who had successful *H. pylori* eradication than in those with persisting infection. Although a number of subsequent studies have raised doubts as to whether a true relationship exists, the available evidence suggests that the prevalence of *H. pylori* infection in patients with GERD is lower than non-GERD control populations and that there is likely an inverse epidemiologic relationship between GERD and *H. pylori*.

The relationship of Barrett esophagus to gastric *H. pylori* colonization is also debated, although most studies show an even stronger inverse relationship than that of GERD alone. Bowrey et al. reported an *H. pylori* prevalence of 27% in patients with Barrett esophagus compared to 41% in healthy control subjects.⁶⁹ Werdmuller and Loffeld⁷⁰ also found significantly lower *H. pylori* infection rates in Barrett than non-Barrett patients (23% vs. 51%), whereas Loffeld et al.⁷¹ reported very high rates (62%) in a retrospective analysis of 107 consecutive patients with CLE. Investigations focused on the role of subpopulations of *H. pylori* have implicated *cagA*⁺ strains as particularly relevant to the development of GE reflux and its complications.⁷² Vicari et al.⁷³ demonstrated that in patients with *H. pylori* infection, the prevalence of *cagA*⁺ strains progressively decreased with the severity of GERD, including Barrett esophagus and esophageal adenocarcinoma. Other studies have confirmed an inverse relationship between the presence of *cagA* positivity and adenocarcinoma of the esophagus and the GE junction.⁷⁴ Most authors postulate that *cagA*⁺ strains may protect from the development of adenocarcinoma by inducing more severe mucosal inflammation and atrophic gastritis and thereby decreasing acid reflux. Present data regarding gastric acid secretion are conflicting, however, and further studies are required to test whether this hypothesis is true.

Previously there was a concept that GERD was a categorical disease with little movement between categories. In other words, patients with nonerosive disease (NERD) seldom developed erosive

esophagitis. This concept was disproven by one of the most detailed studies on the natural history of GERD from investigators in Europe.⁷⁵ The progression or regression of GERD complications was assessed in a cohort of nearly 4,000 patients with predominant heartburn over a 2-year period. After 2 years, 25% of patients with nonerosive GERD progressed to erosive disease, 1.6% with mild erosive esophagitis worsened to more severe esophagitis, and nearly 8% progressed to Barrett esophagus, the latter predominantly in patients with Los Angeles grade C/D erosive disease at baseline. On the other hand, 50% to 60% of patients with baseline esophagitis improved to a milder grade or no erosive disease and 22% were off medications at 2 years. Given that virtually all patients were receiving significant antisecretory therapy, the study shows that a substantial minority of patients will continue to worsen despite pharmacologic treatment. A follow-up study at 5 years on 2,721 of the originally enrolled patients reported that while in most the disease was stable or esophagitis had improved, a sizeable portion of patients progressed.⁷⁶ At 5 years, 6% of patients with NERD, 12% with LA grade A/B esophagitis, and 20% of those with LA grade C/D esophagitis had developed Barrett esophagus. On multivariable analysis risk factors for progression to esophagitis or Barrett esophagus were family history of GERD, baseline esophagitis or remaining unhealed after initial treatment, alcohol intake, and regular use of PPI medication.⁷⁶

Investigators in Lausanne, Switzerland, reported an intensive endoscopic follow-up of a defined population of 959 patients over a 30-year period.⁷⁷ The study involved only patients who had endoscopic esophagitis and did not include those who had symptoms without mucosal injury. In 42% of patients esophagitis progressed on therapy to more severe mucosal injury. Further, 18% of the initial population acquired a columnar-lined lower esophagus with intestinal metaplasia at late follow-up.

Clinical Presentation

The most common complaints in patients with GERD are heartburn, regurgitation, and dysphagia. These represent the so-called typical symptoms of GERD. Although none of these are specific to GERD, dysphagia may be an indication of more serious underlying pathology, including esophageal carcinoma, and should prompt an upper endoscopy. Heartburn means different things to different people and it is important to ask a patient what heartburn means to them. Typically, heartburn should be characterized as a substernal “burning” discomfort often radiating from the epigastrium to sternal notch. Occasionally patients will refer to it as chest or epigastric pain or indigestion. The typical pattern for early reflux disease is heartburn that occurs postprandially and made worse by “spicy” foods such as tomato sauce, citrus juices, chocolate, coffee, and alcohol. It is commonly relieved by antacids, histamine-2 blockers or PPIs. Importantly, the severity of symptoms is not necessarily related to the severity of the underlying disease (Fig. 42-24).

Figure 42-24. Prevalence of erosive esophagitis in 994 patients with varying severity and frequency of reflux symptoms. (Reproduced with permission from Venables TL, Newland RD, Patel AC, et al. Omeprazole 10 mg once daily, omeprazole 20 mg once daily, or ranitidine 150 mg twice daily, evaluated as initial therapy for the relief of symptoms of gastro-oesophageal reflux disease in general practice. *Scand J Gastroenterol* 1997;32:965.)

Regurgitation is the spontaneous return of gastric contents proximal to the GE junction. Its spontaneous nature distinguishes it from vomiting. The patient often gets a sensation that fluid or food is returning into the esophagus, even if it does not reach as high as the pharynx or mouth. It is typically worse at night in the recumbent position or when bending over or lying down after a meal. Patients commonly compensate by not eating late at night or by sleeping partially upright with several pillows

or in a chair. This symptom is often less well relieved with antacids or antisecretory agents, although it may change in character from acidic to a more “bland” nature.

Dysphagia is generally manifested by a sensation of food hanging up in the esophagus rather than difficulty transferring the bolus from the mouth to the esophageal inlet (oropharyngeal dysphagia). Classically, dysphagia limited to only solid food, with normal passage of liquids, suggests a mechanical disorder such as a large hernia, stricture, or tumor, whereas difficulty with both solids and liquids suggests a functional or motor disorder such as achalasia. Dysphagia often develops slowly enough that the patient may adjust his or her eating habits and not be particularly alarmed or aware of the problem. Thus, a thorough esophageal history includes an assessment of the patient’s dietary history. Questions should be asked regarding the consistency of food that is typically eaten and whether the patient requires liquids with the meal, is the last to finish, has interrupted a social meal, chokes or vomits with eating, or has been admitted on an emergency basis for food impaction. These assessments, in addition to the ability to maintain nutrition, help to quantify the dysphagia and are important in determining the indications for surgical therapy.

Many patients with GERD often manifest “atypical” or extraesophageal symptoms, such as cough, asthma, hoarseness, and noncardiac chest pain. Atypical symptoms are the primary complaint in 20% to 25% of patients with GERD and are secondarily present in association with heartburn and regurgitation in many more. It is considerably more difficult to prove a cause-and-effect relationship between atypical symptoms and GE reflux than it is to do so for the typical symptoms, and the etiology of these symptoms is often multifactorial. Often a trial of high-dose PPIs is helpful, but it takes several months to evaluate the full impact of the therapy since if GERD is causing the inflammation that leads to the symptoms, it takes time for that inflammation to improve or resolve with GERD therapy. Antireflux surgery can provide excellent symptom relief in these patients, but careful testing to document GERD is critical particularly in those with little or no response to medical therapy.

The diagnosis of GERD based on symptoms alone is correct in only approximately two-thirds of patients.⁷⁸ This is because these symptoms are not specific for GE reflux and can be caused by other diseases such as achalasia, diffuse spasm, esophageal carcinoma, pyloric stenosis, cholelithiasis, gastritis, gastric or duodenal ulcer, and coronary artery disease. This fact underscores the need for objective diagnosis before the decision is made for surgical treatment.

Physiology of the Antireflux Barrier

The common denominator for virtually all episodes of gastroesophageal reflux, whether physiologic or pathologic, is the loss of the normal gastroesophageal high-pressure zone and the resistance it imposes to the flow of gastric juice from an environment of higher pressure, the stomach, to an environment of lower pressure, the esophagus. This barrier, composed of both anatomic (flap valve and diaphragm) and physiologic (LES) components, acts to prevent reflux during stressed and unstressed conditions. The key determinates of the barrier include:

1. The frequency of swallow- and non-swallow-induced transient relaxations of the LES
2. The structural integrity of the LES
3. Anatomic alterations of the diaphragmatic crura and gastroesophageal flap valve represented by the angle of His

The presence or absence of pathologic esophageal acid exposure (i.e., abnormal 24-hour pH studies) is not only influenced by the degree of barrier loss but also by esophageal and gastric functional characteristics including esophageal clearance, intra-abdominal pressure, and gastric emptying abnormalities.

Transient Relaxation of the Lower Esophageal Sphincter

The lower esophageal high-pressure zone is normally present except in two situations: (a) after a swallow, when it momentarily relaxes to allow passage of food into the stomach, and (b) when the fundus is distended with gas, and it is reflexly relaxed to allow venting of the gas (a belch). In 1982, Dodds et al.⁷⁹ reported that non-swallow-induced transient relaxations of the lower esophageal sphincter (TLESRs) were a significant mechanism of gastroesophageal reflux in normal individuals and patients with GERD. These spontaneous relaxations occurred without pharyngeal contraction, were prolonged (>10 seconds), and, when reflux occurred, were associated with relaxation of the crural diaphragm. Underscoring the importance of the crural diaphragm to barrier integrity, Mittal et al.⁸⁰

later showed that pharmacologic elimination of lower esophageal sphincter pressure to zero did not result in reflux unless crural diaphragmatic contraction was also absent. Gastric distention, upright posture, and meals high in fat have all been shown to increase the frequency of TLESRs.^{80,81} The latter observations suggest that unfolding of the sphincter may be responsible for the loss of sphincter pressure.

As a result of these findings, TLESRs became commonly accepted as the major mechanism of gastroesophageal reflux regardless of the underlying severity of disease, despite evidence to the contrary. The facts that in over 80% of patients with symptomatic gastroesophageal reflux a hiatal hernia could be identified and that most patients with erosive esophagitis and Barrett esophagus had incompetent lower esophageal sphincter characteristics at rest were largely ignored by many. When these facts are taken into account, particularly in association with the known characteristics of TLESRs, it seems likely that transient relaxations are (a) a physiologic response to gastric distention by food or gas, (b) the mechanism of belching, and (c) responsible for physiologic reflux episodes in individuals with normal lower esophageal sphincter and hiatal anatomy, but not the primary mechanism of GERD. Evidence supporting this has been provided via studies of Van Herwaarden et al.,⁸² in which ambulatory esophageal manometry and esophageal pH monitoring were performed on patients with and without hiatal hernia. Patients with hiatal hernia had greater esophageal acid exposure and more reflux episodes, but the frequency of TLESRs, and the proportion associated with reflux, was similar in both groups. They concluded that excess reflux in patients with GERD and hiatal hernia is caused by a combination of low LES pressure, swallow-induced relaxation, and straining.

Structural Integrity of the Lower Esophageal Sphincter

In humans a zone of high pressure can be identified at the junction of the esophagus and stomach. This lower esophageal “sphincter” provides an important component of the barrier between the esophagus and stomach that normally prevents gastric contents from entering the esophagus. It has no anatomic landmarks, but its presence can be identified by a rise in pressure over gastric baseline as a pressure transducer is pulled from the stomach into the esophagus.

There are three characteristics of the lower esophageal sphincter that maintain its resistance or barrier function to intragastric and intra-abdominal pressure challenges. They are its pressure, its overall length, and the length exposed to the positive pressure environment of the abdomen (Table 42-1). The tonic resistance of the lower esophageal sphincter is a function of both its pressure and the length over which this pressure is exerted.²¹ The shorter the overall length of the high-pressure zone, the higher the pressure must be to maintain sufficient resistance to remain competent (Fig. 42-13). Consequently, a short overall sphincter length can nullify a normal sphincter pressure.¹² Further, as the stomach fills, the length of the sphincter decreases, rather like the neck of a balloon shortening as the balloon is inflated. If the overall length of the sphincter is abnormally short when the stomach is empty, then with minimal gastric distention there will be insufficient sphincter length for the existing pressure to maintain sphincter competency, and reflux will occur.

The third characteristic of the lower esophageal sphincter is its position, in that a portion of the overall length of the high-pressure zone should be exposed to positive intra-abdominal pressure. During periods of increased intra-abdominal pressure, the resistance of the lower esophageal sphincter would be overcome if the abdominal pressure were not applied equally to the high-pressure zone and stomach. This is akin to sucking on a soft soda straw immersed in a bottle of Coke; the hydrostatic pressure of the fluid and the negative pressure inside the straw due to sucking cause the straw to collapse instead of allowing the liquid to flow up the straw in the direction of the negative pressure. If the abdominal length is inadequate, the sphincter cannot respond to an increase in applied intra-abdominal pressure by collapsing, and reflux is more liable to result. If the high-pressure zone has an abnormal low pressure, a short overall length, or minimal exposure to the abdominal pressure environment in the fasting state, then there is a permanent loss of lower esophageal sphincter resistance and the unhampered reflux of gastric contents into the esophagus throughout the circadian cycle. This is referred to as a *permanently defective sphincter* and is identified by having one or more of the following characteristics: a high-pressure zone with an average pressure of less than 6 mm Hg, an average overall length of 2 cm or less, and an average length exposed to the positive pressure environment of the abdomen of 1 cm or less.⁸³ Compared with normal subjects, these values are below the 2.5th percentile for each parameter. The most common cause of a permanently defective sphincter is an inadequate abdominal length, most likely a consequence of the development of a hiatal hernia. It is important to note that an inadequate abdominal length or an abnormally short overall length can nullify the efficiency of a sphincter with a

normal pressure.

The presence of a permanently defective sphincter has several implications. First, it is commonly associated with esophageal mucosal injury and predicts that the patient's symptoms may be difficult to control with medical therapy.^{23,34} It is now accepted that when the sphincter is permanently defective, it is irreversible, even when the associated esophagitis is healed. The presence of a permanently defective sphincter is commonly associated with reduced esophageal body function,⁸⁴ and if the disease is not brought under control, the progressive loss of effective esophageal clearance can lead to severe mucosal injury, repetitive regurgitation, aspiration, and pulmonary failure.

Anatomic Alterations

With the advent of clinical roentgenology, it became evident that a hiatal hernia was a relatively common abnormality although not always accompanied by symptoms. Philip Allison, in his classic treatise published in 1951, suggested that the manifestations of GERD were caused by the presence of a hiatal hernia. For most of the next two decades, hiatal hernia was considered the primary pathophysiologic abnormality leading to GERD. Indeed, the Allison repair, among the first surgical attempts to treat GERD, consisted of a hernia repair only. As techniques of esophageal manometry were developed in the late 1950s and 1960s, allowing identification and study of the lower esophageal sphincter, attention was slowly diverted away from the hernia as the main pathophysiologic abnormality of GERD. In 1971, Cohen and Harris⁸⁵ published a study of the contributions of hiatal hernia to lower esophageal sphincter competence in 75 patients, concluding that hiatal hernia had no effect on GE junction competence. This paper, published in the *New England Journal of Medicine*, and the growing use of esophageal manometry shifted the emphasis away from the hernia almost exclusively toward features of the lower esophageal sphincter as the primary abnormality in symptomatic GERD.

Perhaps serendipitously, studies of the phenomenon of TLESRs identified the diaphragmatic crura as an important factor in preventing reflux during periods of loss of LES pressure.⁸⁶ In normal subjects, even with absent LES pressure, reflux does not occur without relaxation of the crural diaphragm. Coincidentally, Hill et al.⁸⁷ stressed the importance of the physiologic flap valve created by the angle of His as a barrier to gastroesophageal reflux. The endoscopic appearance of the flap valve can be correlated with abnormal esophageal acid exposure, emphasizing that the geometry of the gastroesophageal region is also important to barrier competence.⁴⁷ If mechanical forces set in play by gastric distention are important in pulling on the terminal esophagus and shortening the length of the high-pressure zone or "sphincter," then the geometry of the cardia, that is, the presence of a normal acute angle of His or the abnormal dome architecture of a sliding hiatus hernia, should influence the ease with which the sphincter is pulled open. Evidence that this occurs was provided by Ismail et al.,¹⁶ who showed a close relationship between the degree of gastric distention necessary to overcome the high-pressure zone (yield pressure) and the morphology of the cardia (Fig. 42-25). No relationship between the yield pressure and lower esophageal sphincter resting pressure and length was found. A higher intragastric pressure was needed to open the sphincter in patients with an intact angle of His when compared to patients with a hiatal hernia. The presence of a hiatal hernia also disturbs esophageal clearance mechanisms likely due to loss of anchorage of the esophagus in the abdomen. Kahrilas et al. have shown that complete esophageal emptying was achieved in 86% of swallows in control subjects without a hiatal hernia, 66% in patients with a reducing hiatal hernia, and only 32% of patients with a nonreducing hiatal hernia.⁸⁸ Impaired clearance in patients with nonreducing hiatal hernias further supports the contribution of hiatal hernia to the pathogenesis of GERD. Thus, present evidence is overwhelming that hiatal hernia does indeed play a significant, if not primary, role in the pathophysiology of GERD.

Figure 42-25. The intragastric pressure at which the lower esophagus endoscopically opened in response to gastric distention by air during endoscopy. Note that the dome architecture of a hiatus hernia (HH) influences the ease with which the sphincter can be pulled open by gastric distention. (Reproduced with permission from Ismail T, Bancewicz J, Barlow J. Yield pressure, anatomy of the cardia and gastro-oesophageal reflux. *Br J Surg* 1995;82:943–947.)

A transient loss of the high-pressure zone can also occur and usually results from a functional problem of the gastric reservoir.³³ Excessive air swallowing or food can result in gastric dilatation and, if the active relaxation reflex has been lost, an increased intragastric pressure. When the stomach is distended, the vectors produced by gastric wall tension pull on the GE junction with a force that varies according to the geometry of the cardia; that is, the forces are applied more directly when a hiatal hernia exists than when a proper angle of His is present. The forces pull on the terminal esophagus, causing it to be “taken up” into the stretched fundus and thereby reducing the length of the high-pressure zone or “sphincter.” This process continues until a critical length is reached, usually about 1 to 2 cm, when the pressure drops precipitously and reflux occurs. The mechanism by which gastric distention contributes to shortening of the length of the high-pressure zone, so that its pressure drops and reflux occurs, provides a mechanical explanation for “transient relaxations” of the LES without invoking a neuromuscular reflex. Rather than a “spontaneous” muscular relaxation, there is a mechanical shortening of the high-pressure zone, secondary to progressive gastric distention, to the point where it becomes incompetent. These “transient sphincter” shortenings occur in the initial stages of GERD and are the mechanism for the early complaint of excessive postprandial reflux. After gastric venting, the length of the high-pressure zone is restored and competence returns until distention again shortens it and encourages further venting and reflux. This sequence results in the common complaints of repetitive belching and bloating in patients with GERD. The increased swallowing frequency seen in patients with GERD contributes to gastric distention and is due to their repetitive ingestion of saliva in an effort to neutralize the acid refluxed into their esophagus.²⁶ Thus, GERD may begin in the stomach, secondary to gastric distention resulting from overeating and the increased ingestion of fried foods, which delay gastric emptying. Both characteristics are common in Western society and may explain the high prevalence of the disease in the Western world.

A recent series of studies from Glasgow assesses the nature of the acid environment at the GE junction,²⁸ including possible inciting factors in the development of cardia and distal esophageal adenocarcinoma. The studies were initiated to investigate a long-recognized observation that esophageal pH monitoring reveals postprandial esophageal acidification at the same time as the gastric contents are alkalinized. This paradox is hard to explain given that reflux of gastric content into the esophagus is the primary mechanism underlying GERD. Hypothesizing that acidic material must be present somewhere in the upper stomach, the investigators studied luminal pH at 1-cm increments across the upper stomach and lower esophagus in healthy volunteers before and after meals. Surprisingly, they identified a “pocket” of acid at the GE junction unaffected by the buffering action of the meal, which extended across the squamocolumnar junction an average of 1.8 cm into the lumen of the esophagus (Fig. 42-26). The authors concluded that this was the source of postprandial esophageal acid exposure. They expanded these initial studies, confirming that the same process occurs in patients with endoscopy-negative dyspepsia and normal conventional esophageal pH monitoring 5 cm above the upper border of the LES.⁸⁹ Perhaps more important, they also identified that dietary nitrate consumed in the form of green vegetables results in the generation of concentrations of nitric oxide at the GE junction high

enough to be potentially mutagenic (Fig. 42-27).⁹⁰ These observations provide the fundamental basis for the observations of inflammation and other alterations in the epithelium long known to occur at the squamocolumnar junction in both overt and unrecognized GERD.

Figure 42-26. Fasting and postprandial gastric and esophageal pH measurements in 1 cm increments during a pull through the gastroesophageal junction. The postprandial tracing reveals an “acid pocket” from 44 to 41 cm from the nares. The fasting tracing reveals this to be the same area as the pH “step-up” corresponding to the transition from the stomach to the esophagus. (Reproduced with permission from Fletcher J, Wirz A, Young J, et al. Unbuffered highly acidic gastric juice exists at the gastroesophageal junction after a meal. *Gastroenterology* 2001;121:775–783.)

Figure 42-27. Mean ($\pm$ SEM) nitric oxide concentrations in the upper stomach and lower esophagus after administration of water with 2 mmol nitrate (upper tracing) and water alone (lower tracing) (** $p < 0.01$, * $p < 0.05$ compared with value at gastroesophageal junction pH step-up). (Reproduced with permission from Iljima K, Henry E, Moriya A, et al. Dietary nitrate generates potentially mutagenic concentrations of nitric oxide at the gastroesophageal junction. *Gastroenterology* 2002;122:1248–1257.)

The data support the likelihood that GERD begins in the stomach. Fundic distention occurs because of overeating and delayed gastric emptying secondary to the high-fat Western diet. The distention causes the sphincter to be “taken up” by the expanding fundus, exposing the squamous epithelium with the high-pressure zone, which is the distal 3 cm of the esophagus, to gastric juice. Repeated exposure causes inflammation of the squamous epithelium, columnarization, and carditis. This is the initial step and explains why in early disease the esophagitis is mild and commonly limited to the very distal esophagus. The patient compensates by increased swallowing, allowing saliva to bathe the injured mucosa and alleviate the discomfort induced by exposure to gastric acid. Increased swallowing results in aerophagia, bloating, and repetitive belching. The distention induced by aerophagia leads to further exposure and repetitive injury to the terminal squamous epithelium and the development of cardiac-type mucosa. This is an inflammatory process, commonly referred to as “carditis,” and explains the complaint of epigastric pain so often registered by patients with early disease. The process can lead to a fibrotic mucosal ring at the squamocolumnar junction and explains the origin of a Schatzki ring. Extension of the inflammatory process into the muscularis propria causes a progressive loss in the length and pressure of the distal esophageal high-pressure zone associated with an increased esophageal exposure to gastric juice and the symptoms of heartburn and regurgitation. The loss of the barrier occurs in a distal-to-proximal direction and eventually results in the permanent loss of LES resistance and the explosion of the disease into the esophagus with all the clinical manifestations of severe esophagitis. This accounts for the observation that severe esophageal mucosal injury is almost always associated with a permanently defective sphincter. At any time during this process and under specific luminal conditions or stimuli, such as

exposure time to a specific pH range, intestinalization of the cardiac-type mucosa can occur and set the stage for malignant degeneration.

Implications

Implications of recognizing anatomic alterations as component of GE barrier:

- 1. Transient lower esophageal sphincter relaxation is likely a consequence of sphincter shortening by gastric distention and is the underlying mechanism for belching and physiologic reflux. It does not play a major role in patients with symptomatic gastroesophageal reflux, particularly those with erosive disease, Barrett esophagus, or those referred for surgery.
- 2. Efforts to augment the gastroesophageal barrier either pharmacologically or endoscopically will commonly fail when a hiatal hernia is present.
- 3. Patients with abnormal esophageal acid exposure in the presence of normal LES characteristics and no hiatal hernia have an uncommon reason for reflux and these patients require additional evaluation since gastric or esophageal clearance failure may be present and may impair the outcome of a fundoplication.
- 4. Both reduction of hiatal hernia and augmentation of the lower esophageal sphincter are necessary to maximally restore gastroesophageal barrier competence.
- 5. Although acid control without regard to barrier incompetence will improve heartburn and heal esophageal erosive disease, it results in increasing numbers of patients with pulmonary manifestations of GERD.

Complications of Gastroesophageal Reflux Disease

The complications of gastroesophageal reflux result from the damage caused by the reflux of gastric juice onto the esophageal mucosa or laryngeal or respiratory epithelium (Fig. 42-28). Complications can be conceptually divided into (a) mucosal complications such as esophagitis and stricture; (b) extraesophageal or respiratory complications such as chronic cough, asthma, and pulmonary fibrosis; and (c) metaplastic (Barrett esophagus) and neoplastic (adenocarcinoma). The prevalence and severity of complications is related to the degree of loss of the gastroesophageal barrier, defects in esophageal clearance, and the content of refluxed gastric juice (Fig. 42-29).

Figure 42-28. Schematic representation of the types of complications of gastroesophageal reflux disease.

Figure 42-29. Prevalence of esophageal mucosal injury related to the presence of a defective lower esophageal sphincter,

Mucosal Complications

The potential injurious components that reflux into the esophagus include gastric secretions, such as acid and pepsin; biliary and pancreatic secretions that regurgitate from the duodenum into the stomach; and toxic compounds generated in the mouth, esophagus, and stomach by the action of bacteria on dietary substances.

Our current understanding of the role of the various ingredients of gastric juice in the development of esophagitis is based on classic animal studies performed by Lillimoe et al.^{91,92} These studies have shown that acid alone does minimal damage to the esophageal mucosa, but the combination of acid and pepsin is highly deleterious. Hydrogen ion injury to the esophageal squamous mucosa occurs only at a pH below 2. In acid refluxate, the enzyme pepsin appears to be the major injurious agent. Similarly, the reflux of duodenal juice alone does little damage to the mucosa, while the combination of duodenal juice and gastric acid is particularly noxious. Reflux of bile and pancreatic enzymes into the stomach can either protect or augment esophageal mucosal injury. For instance, the reflux of duodenal contents into the stomach may prevent the development of peptic esophagitis in a patient whose gastric acid secretion maintains an acid environment, because the bile salts would attenuate the injurious effect of pepsin and the acid would inactivate the trypsin. Such a patient would have bile-containing acid gastric juice that, when refluxed, would irritate the esophageal mucosa but cause less esophagitis than if it were acid gastric juice–containing pepsin. In contrast, the reflux of duodenal contents into the stomach of a patient with limited gastric acid secretion can result in esophagitis, because the alkaline intragastric environment would support optimal trypsin activity and the soluble bile salts with a high pK_a would potentiate the enzyme's effect. Hence, duodenal-gastric reflux and the acid-secretory capacity of the stomach interrelate by altering the pH and enzymatic activity of the refluxed gastric juice to modulate the injurious effects of enzymes on the esophageal mucosa.

This disparity in injury caused by acid and bile alone as opposed to the gross esophagitis caused by pepsin and trypsin provides an explanation for the poor correlation between the symptom of heartburn and endoscopic esophagitis. The reflux of acid gastric juice contaminated with duodenal contents could break the esophageal mucosal barrier, irritate nerve endings in the papillae close to the luminal surface, and cause severe heartburn. Despite the presence of intense heartburn, the bile salts present would inhibit pepsin, the acid pH would inactivate trypsin, and the patient would have little or no gross evidence of esophagitis. In contrast, the patient who refluxed alkaline gastric juice may have minimal heartburn because of the absence of hydrogen ions in the refluxate but have endoscopic esophagitis because of the bile salt potentiation of trypsin activity on the esophageal mucosa. This is supported by recent clinical studies that indicate that the presence of alkaline reflux is associated with the development of mucosal injury.⁹³

Although numerous studies have suggested the reflux of duodenal contents into the esophagus in patients with GERD, few have measured this directly. The components of duodenal juice thought to be most damaging are the bile acids, and as such, they have been the most commonly studied. Most studies have implied the presence of bile acids using pH measurements. Studies using either prolonged ambulatory aspiration techniques (Fig. 42-30) or spectrophotometric bilirubin measurement have shown that, as a group, patients with GERD have greater and more concentrated bile acid exposure to the esophageal mucosa than normal subjects.^{23,34} This increased exposure occurs most commonly during the supine period while asleep and during the upright period following meals. Most studies have identified the glycine conjugates of cholic, deoxycholic, and chenodeoxycholic acids as the predominant bile acids aspirated from the esophagus of patients with GERD, although appreciable amounts of taurine conjugates of these bile acids were also found. Other bile salts were identified but in small concentrations. This is as one would expect because glycine conjugates are three times more prevalent than taurine conjugates in normal human bile.

The potentially injurious action of toxic compounds either ingested or newly formed on the mucosa of the gastroesophageal junction and distal esophagus has long been postulated. Until recently, however, few studies have substantiated this possibility. Expanding upon studies of acid exposure at the gastroesophageal junction, investigators from Glasgow, Scotland, have recently shown that dietary nitrate consumed in the form of green vegetables and food contaminated by nitrate-containing fertilizers results in the generation of nitric oxide at the gastroesophageal junction in concentrations high enough to be potentially mutagenic.⁹⁰ Previous studies have shown that nitrate ingested in food is reabsorbed in the small bowel, with approximately 25% resecreted into the mouth via the salivary

glands. Oral bacteria chemically transforms the relatively innocuous nitrate to the more toxic nitrite, which is swallowed and subsequently converted to nitric oxide and other toxic nitroso-compounds by acid and ascorbic acid in the stomach. Whether this mechanism in fact contributes to injury and/or neoplastic transformation in the upper stomach, gastroesophageal junction, and distal esophagus is currently unknown.

Respiratory Complications

It is increasingly recognized that a significant proportion of patients with gastroesophageal reflux will have either primary RSs or RSs in association with more prominent heartburn and regurgitation.⁹⁴ Reflux has been implicated as causative of asthma and idiopathic pulmonary fibrosis (IPF) and can complicate advanced lung diseases including chronic obstructive pulmonary disease (COPD) and cystic fibrosis (CF). Thirty-five to fifty percent of asthmatics have been shown to have abnormal esophageal pH, esophagitis, and a hiatal hernia.⁹⁵ Others have shown that the prevalence of reflux symptoms exceeded 50% in patients with asthma and CF.^{96,97} In addition, patients with COPD and gastroesophageal reflux are twice as likely to have significant COPD exacerbations than their nonreflux counterparts,⁹⁸ and reflux symptoms correlate with airway obstruction in COPD patients. These reports suggest that the frequency of dual pathology is higher than would be expected by chance alone.

Pathophysiology of Reflux-Induced Respiratory Symptoms. Two mechanisms have been proposed as the pathogenesis of reflux-induced RSs. The first, the so-called “reflux” theory, maintains that RSs are the result of the aspiration or microaspiration of gastric contents. The second or “reflex” theory maintains that vagally mediated bronchoconstriction follows acidification of the lower esophagus via a reflex neurologic arc.

The evidence supporting a *reflux* mechanism was shown in animals in the 1950s to 1970s, with studies of acid instillation in the lungs resulting in pneumonitis,^{99,100} epithelial damage,¹⁰¹ and increased airway resistance.¹⁰² The evidence in humans can be categorized as follows. First, there is radiographic evidence. Patients with pulmonary fibrosis have an increased prevalence of hiatal hernia on upper GI series,^{103,104} while elderly patients with large hiatal hernias have a significantly increased frequency of pleural scarring on chest CT scans.¹⁰⁵ Second, erosive esophagitis was found at a high frequency in a large series of Veterans Affairs patients with asthma, pneumonia, chronic bronchitis, and pulmonary fibrosis.⁹⁴ Third, patients with chronic lung diseases, including asthma and pulmonary fibrosis in particular, have a significantly higher frequency of positive 24-hour pH studies.^{105,106} With dual pH monitoring of the proximal and distal esophagus, prolonged exposure of the proximal esophagus to gastric juice occurs at a higher frequency in patients with gastroesophageal reflux and RSs than in patients without respiratory complaints.^{107,108} Fourth, simultaneous tracheal and esophageal pH monitoring in patients with reflux disease have documented tracheal acidification in concert with esophageal acidification.¹⁰² Finally, medications used to treat chronic lung diseases, in particular, bronchodilators, relax esophageal sphincter tone.¹⁰⁹

A *reflex* mechanism is primarily supported by the fact that bronchoconstriction occurs following the infusion of acid into the lower esophagus.^{110–112} This can be explained by the common embryologic

origin of the tracheoesophageal tract and its shared vagal innervation.

The primary challenge in implementing treatment for reflux-associated RSs lies in establishing the diagnosis. In those patients with predominantly typical reflux symptoms and secondary respiratory complaints, the diagnosis may be straightforward. However, in a substantial number of patients with reflux-induced RSs, the RSs dominate the clinical scenario. Gastroesophageal reflux in these patients is often silent and is only uncovered when investigation is initiated.^{106,113} A high index of suspicion is required, notably in patients with poorly controlled asthma in spite of appropriate bronchodilator therapy. Supportive evidence for the diagnosis can be gleaned from endoscopy and stationary esophageal manometry. Endoscopy may show erosive esophagitis or Barrett esophagus. Manometry may indicate a hypotensive lower esophageal sphincter or ineffective body motility, defined by 30% or more contractions in the distal esophagus of less than 30 mm Hg in amplitude.¹¹⁴ D'Ovidio et al.¹¹⁵ studied 78 patients awaiting lung transplant for IPF, scleroderma, COPD, or CF and found that 72% had a hypotensive lower esophageal sphincter, 33% abnormal esophageal body motility, and 38% abnormal 24-hour pH testing, although, interestingly, patients with IPF in other series have been shown to have normal manometry.¹⁰⁸

The current “gold standard” for the diagnosis of reflux-induced respiratory complaints is ambulatory dual-probe pH monitoring, often combined with multichannel intraluminal impedance (MII-pH). One probe is positioned in the distal esophagus and the other at a more proximal location. Sites for proximal probe placement have included the trachea, pharynx, and proximal esophagus. Most authorities would agree that the proximal esophagus is the preferred site for proximal probe placement. While ambulatory esophageal pH monitoring allows a direct correlation between esophageal acidification and RSs, the chronologic relationship between reflux events and bronchoconstriction is complex. Further, the proximal probe must be positioned close to, but not above, the UES. Failure to properly place the probe can lead to artifact or errors in pH assessment. In addition, the use of a pH threshold of 4 as is used in the distal esophagus is questioned. Normal subjects should have a pH ≥ 7 in the cervical esophagus for at least 19.6% of the monitored period. Looking at pH exposure in reverse, in other words as loss of the normal alkalinity in the cervical esophagus, was shown to be a more sensitive indicator of proximal reflux.¹¹⁶ Recently the use of a special pH probe designed for the environment of the pharynx has been advocated in patients with RSs to evaluate for proximal reflux. This probe, called the Restech pH probe (Respiratory Technology Corp, San Diego, CA, USA), has been shown to better predict successful relief of extraesophageal RSs with a fundoplication compared to the traditional dual-probe pH test.¹¹⁷ Of importance, the Restech analysis uses a pH threshold of 5.5 for upright and 5.0 for supine reflux, and the Ryan score is used to determine normal from abnormal pharyngeal reflux exposure.¹¹⁶ Probably the best pH monitoring method in these patients is to start with a 48-hour Bravo pH and if that is normal on both days then add a Restech pH test.¹¹⁷

Laryngopharyngeal Reflux

The term *LPR* is used for a broad category of atypical symptoms that may be secondary to gastroesophageal reflux. These may include laryngitis, pharyngitis, hoarseness, sinusitis, sleep disturbance, dental erosions, and globus.^{118,119} Mechanisms for these symptoms are difficult to prove and substantial evidence remains lacking.¹²⁰

Treatment of Extraesophageal Complications. Once gastroesophageal reflux is suspected or thought to be responsible for extraesophageal symptoms, treatment may be with either prolonged PPI therapy or antireflux surgery. Initially, a 3- to 6-month trial of high-dose PPI therapy (b.i.d. or t.i.d. dosing) may help confirm (by virtue of symptom resolution) the fact that reflux is partly or completely responsible for the symptoms. If symptoms are improved, patients can be treated with maintenance medical therapy or may be offered surgical treatment to control the reflux. The persistence of symptoms despite PPI treatment, however, does not necessarily rule out reflux as being a potential contributor. [Algorithm 42-1](#) bases clinical decisions on the results of dual-probe 24-hour pH monitoring and is a useful starting point.

Algorithm 42-1

Algorithm 42-1. 24-Hour Esophageal pH Monitoring

Based on reported observations, relief of RSs can be anticipated for 25% to 50% of patients with reflux-induced asthma treated with antisecretory medications,^{121–123} although patients with pulmonary fibrosis in particular may have an inherent resistance to standard-dose PPIs.¹²⁴ Fewer than 15% of asthmatics with symptom relief, however, can be expected to have objective improvements in their pulmonary function. The reason for this apparent paradox may be that most studies employed relatively short courses of antisecretory therapy (<3 months). This time period may have been sufficient for symptomatic improvement but insufficient for recovery of pulmonary function. The chances of success with medical treatment are likely directly related to the extent of reflux elimination. The conflicting findings of reports of antisecretory therapy may well be due to inadequate control of gastroesophageal reflux in some studies. The literature indicates that antireflux surgery improves RSs in nearly 90% of children and 70% of adults with asthma and reflux disease.^{123,125} Improvements in pulmonary function were demonstrated in around one-third of patients. Comparison of the results of uncontrolled studies of each form of therapy and the evidence from the two randomized controlled trials of medical versus surgical therapy indicate that fundoplication is the most effective therapy for reflux-induced asthma.¹²⁵ The superiority of the surgical antireflux barrier over medical therapy is probably most noticeable in the supine posture, which corresponds with the period of acid breakthrough with PPI therapy and is the time in the circadian cycle when asthma symptoms and peak expiratory flow rates are at their worst.

More convincing data establishing the benefit of antireflux surgery in improving RSs and pulmonary function tests derives from the lung transplantation literature. Bronchiolitis obliterans syndrome (BOS), synonymous with chronic rejection of the transplanted lung, is diagnosed by a greater than 20% decline in pulmonary function tests from posttransplant baseline. Lau et al. showed in the early 2000 that 67% of 18 patients with BOS had an improvement in their pulmonary function tests after antireflux surgery.¹²⁶ More recently, several groups have reported improvements in oxygen requirements and stabilization of declining pulmonary function tests when pre-lung transplant patients underwent antireflux surgery.^{127,128} In addition, pulmonary and other extraesophageal symptoms can improve after laparoscopic Nissen fundoplication with minimal perioperative morbidity.¹²⁹

It is also important to realize that, in asthmatic patients with a non-reflux-induced motility abnormality of the esophageal body, performing an antireflux operation may not prevent the aspiration of orally regurgitated, swallowed liquid or food. This can result in RSs and airway irritation that may elicit an asthmatic reaction. This factor may be the explanation why surgical results appear to be better in children than adults, since disturbance of esophageal body motility is more likely in adult patients.

Metaplastic (Barrett) and Neoplastic (Adenocarcinoma) Complications

The condition whereby the tubular esophagus is lined with columnar epithelium rather than squamous epithelium was first described by Norman Barrett in 1950 (Fig. 42-31).¹³⁰ He incorrectly believed it to be congenital in origin. It is now realized that it is an acquired abnormality, occurring in 7% to 10% of patients with GERD, and represents the end stage of the natural history of this disease.¹³¹ It is also understood to be distinctly different from the congenital condition in which islands of mature gastric columnar epithelium are found in the upper half of the esophagus.

The definition of Barrett esophagus has evolved considerably over the past decade.^{130–133} Traditionally, Barrett esophagus was identified by the presence of any columnar mucosa extending at

least 3 cm into the esophagus. Recent data indicating that specialized intestinal-type epithelium is the only tissue predisposed to malignant degeneration, coupled with the finding of a similar risk of malignancy in segments of intestinal metaplasia less than 3 cm long, have resulted in the diagnosis of Barrett esophagus, given any length of endoscopically visible tissue that is intestinal metaplasia on histology (Fig. 42-32). Whether to call long segments of columnar mucosa without intestinal metaplasia Barrett esophagus is unclear. The hallmark of intestinal metaplasia is the presence of goblet cells. Recent studies have identified a high prevalence of biopsy-proven intestinal metaplasia at the cardia, in the absence of endoscopic evidence of a CLE. The significance and natural history of this finding remain unknown. The term *Barrett esophagus* should currently be used in the setting of an endoscopically visible segment of intestinal metaplasia of any length or columnar replacement of the esophagus of 3 cm or more.

Figure 42-31. Endoscopic appearance of Barrett esophagus. Note the pink metaplastic mucosa as opposed to the normal whitish squamous lining of the esophagus.

Factors predisposing to the development of Barrett esophagus include early-onset GERD, abnormal lower esophageal sphincter and esophageal body physiology, and mixed reflux of gastric and duodenal contents into the esophagus.¹³³ Direct measurement of esophageal bilirubin exposure as a marker for duodenal juice has shown that 58% of the patients with GERD have increased esophageal exposure to duodenal juice and that this exposure is most dramatically related to Barrett esophagus.¹³⁴

Pathophysiology of Barrett Metaplasia. Recent studies suggest that the metaplastic process at the gastroesophageal junction may begin by conversion of distal esophageal squamous mucosa to cardiac-type epithelium, heretofore presumed to be a normal finding.¹³² This is likely due to exposure of the distal esophagus to excess acid and gastric contents via prolapse of esophageal squamous mucosa into the gastric environment. This results in inflammatory changes at the gastroesophageal junction and/or a metaplastic process, both of which may result in the loss of muscle function and a mechanically defective sphincter allowing free reflux with progressively higher degrees of mucosal injury. Intestinal metaplasia within the sphincter may result, as in Barrett metaplasia of the esophageal body. This mechanism is supported by the finding that as the severity of GERD progresses, the length of columnar lining above the anatomic gastroesophageal junction is increased.

Figure 42-32. Histologic appearance of Barrett esophagus. To the left of the photograph, columnar mucosa with abundant goblet

cells is seen. This is intestinal metaplasia, which is the histologic hallmark of Barrett esophagus. To the right of the photomicrograph, cardiac epithelium is present.

Treatment. The relief of symptoms remains the primary force driving antireflux surgery in patients with Barrett esophagus. Healing of esophageal mucosal injury and the prevention of disease progression are important secondary goals. In this regard, patients with Barrett esophagus are no different than the broader population of patients with gastroesophageal reflux. Antireflux surgery should be considered when patient factors suggest severe disease or predict the need for long-term medical management, both of which are almost always true in patients with Barrett esophagus.

PPI therapy, both to relieve symptoms and to control any coexistent esophagitis or stricture, is an acceptable treatment option in patients with Barrett esophagus. Once initiated, however, most patients with Barrett esophagus will require life-long treatment. Complete control of reflux with PPI therapy can be difficult, however, as has been highlighted by studies of acid breakthrough while on therapy. Katzka and Castell, and Ouatu-Lascar and Triadafilopoulos have shown that 40% to 80% of patients with Barrett esophagus continue to experience abnormal esophageal acid exposure despite up to 20 mg twice daily of PPI.^{135,136} Ablation trials have shown that mean doses of 56 mg of omeprazole are necessary to normalize 24-hour esophageal pH studies.¹³⁷ Antireflux surgery likely results in more reproducible and reliable elimination of reflux of both acid and duodenal content, although long-term outcome studies suggest that as many as 25% of patients postfundoplication will have persistent pathologic esophageal acid exposure confirmed by 24-hour pH studies.¹³⁸

An important consideration is that patients with Barrett esophagus generally have severe GERD, with its attendant sequelae such as large hiatal hernia, stricture, shortened esophagus, and poor motility. Compared to mild and nonerosive reflux disease, severe erosive disease and Barrett esophagus are associated with significantly greater loss of the mechanical antireflux barrier because of associated hiatal hernias and a hypotensive lower esophageal sphincter. Surgical treatment with a laparoscopic Nissen fundoplication reduces the hiatal hernia, improves the antireflux barrier, and consequently provides similarly excellent symptom control.¹³⁹ Large studies in patients with typical acid reflux symptoms have been published from the United States and Europe.^{140–143} In patients having laparoscopic Nissen fundoplication at Emory University, relief of heartburn and regurgitation occurred in 90%, and 70% were off all reflux medications at a mean follow-up of 11 years.¹⁴⁴ These results emphasize the durability of the procedure as well as the persistent relief of typical symptoms. Risk factors for persistent use of antacids after antireflux surgery include a partial fundoplication, older age, and female gender.¹⁴⁵

Studies focusing on the symptomatic outcome following antireflux surgery in patients with Barrett esophagus document excellent to good results in 72% to 95% of patients at 5 years following surgery.^{138–140} The outcome of laparoscopic Nissen fundoplication in patients with Barrett esophagus has been assessed at 1 to 3 years after surgery. Hofstetter et al. reported the experience at the University of Southern California (USC) in 85 patients with Barrett esophagus at a median of 5 years after surgery. Fifty-nine had long- and 26 short-segment Barrett esophagus and 50 underwent a laparoscopic antireflux procedure.¹³⁸ Reflux symptoms were absent postoperatively in 79% of the patients. Postoperative 24-hour pH was normal in 17 of 21 patients (81%). Ninety-nine percent of the patients considered themselves cured or improved and 97% were satisfied with the surgery. In addition to symptomatic improvement in reflux after surgery, there is evidence that mediators of esophageal inflammation implicated in carcinogenesis are decreased as well. Cyclooxygenase-2 (COX-2) gene expression is elevated in the distal esophagus of reflux patients, but the expression of COX-2 and another inflammatory mediator, interleukin 8, can be decreased in the distal esophageal mucosa after a fundoplication.^{146–148}

Figure 42-33. Histologic appearance of Barrett esophagus. To the left of the photograph, columnar mucosa with abundant goblet cells is seen. This is intestinal metaplasia, which is the histologic hallmark of Barrett esophagus. To the right of the photomicrograph, cardiac epithelium is present.

The Development of Dysplasia in Barrett Esophagus. The prevalence of dysplasia at diagnosis in patients presenting with Barrett esophagus ranges from 15% to 25%, and approximately 5% of patients will develop dysplasia each year. The identification of dysplasia in Barrett epithelium rests on histologic examination of biopsy specimens. The cytologic and tissue architectural changes are similar to those described in ulcerative colitis (Fig. 42-33). By convention, Barrett metaplasia is currently classified into four broad categories:

1. No dysplasia
2. Indefinite for dysplasia
3. Low-grade dysplasia
4. High-grade dysplasia

There are few prospective studies documenting the progression of nondysplastic Barrett epithelium to low- or high-grade dysplasia. Those that are available suggest that 5% to 6% per year will progress to dysplasia and 0.5% to 1% per year to adenocarcinoma (Table 42-2). Several newer studies have suggested a lower rate, but these studies excluded patients that progressed within the first year of follow-up, and in one study included those with a CLE with or without intestinal metaplasia. Once identified, Barrett esophagus complicated by dysplasia should undergo aggressive therapy. Patients whose biopsies are interpreted as indefinite for dysplasia should be treated with a medical regimen consisting of 60 to 80 mg of PPI therapy for 3 months and rebiopsied. Importantly, esophagitis should be healed prior to interpretation of the presence or absence of dysplasia. The presence of severe inflammation makes the microscopic interpretation of dysplasia difficult. The purpose of acid suppression therapy is to resolve inflammation that may complicate the interpretation of the biopsy specimen. Persistent indefinite or low-grade dysplasia should be a relative indication for a Nissen fundoplication given the evidence that in most patients low-grade dysplasia reverts to nondysplastic intestinal metaplasia after a fundoplication. Alternatively, or if dysplasia persists after a fundoplication, it should be ablated using radiofrequency or cryotherapy devices given evidence that ablation reduces the risk of progression to cancer in these patients.

DIAGNOSIS

Table 42-2 Development of Dysplasia: Prospective Evaluation of 62 Patients

Initial Diagnosis	Final Diagnosis				
	No.	Metaplasia	I/LGD	HGD	CA
Metaplasia	39	27	10	1	1
I/LGD	20	4	8	3	2
HGD	3			1	2

CA, carcinoma; HGD, high-grade dysplasia; I, indeterminate; LGD, low-grade dysplasia.
 From Reid BJ, Blount PL, Rubin CE, et al. Flow-cytometric and histological progression to malignancy in Barrett's esophagus: prospective endoscopic surveillance of a cohort. *Gastroenterology* 1992;102:1212-1219.

HGD should be confirmed by two pathologists knowledgeable in GI pathology. Numerous esophagectomy series have shown that approximately 50% of patients thought to have only HGD will harbor a focus of invasive carcinoma somewhere in the columnar mucosa.¹⁴⁹⁻¹⁵¹ Any patient with dysplasia, particularly HGD, requires careful endoscopic evaluation preferably with a high-definition endoscope and NBI or similar technology to look for any nodules or lesions. These lesions are sites of potential invasive cancer. If no lesion is present then the columnar mucosa should be ablated since randomized trials have confirmed the benefit of ablation to reduce the risk of progression to cancer in patients with HGD.

If a lesion is present it must be excised using ER techniques to determine if it is malignant and allow assessment of the depth of invasion and tumor characteristics. The aim of EMR is to excise the area of interest including the mucosal and submucosal layers down to the muscularis propria allowing optimal histologic interpretation. Over a decade ago the authors showed in a small series that EMR reliable

removed superficial esophageal adenocarcinomas and provided an excellent pathologic specimen for evaluation. Until recently, esophagectomy was considered the standard of care for patients with HGD or a superficial adenocarcinoma. Subsequently, high-volume esophageal centers in Europe and the United States began offering endoscopic therapy for these lesions in appropriate patients. The authors have confirmed that the oncologic outcome is similar in patients with HGD or intramucosal adenocarcinoma whether they were treated with esophagectomy or endoscopic therapy, but the morbidity and mortality rates were significantly lower with endoscopic therapy. The largest study on endoscopic therapy alone for intramucosal adenocarcinoma comes from Wiesbaden, Germany. In this study of 1,000 patients there was no procedure-related mortality and only a 2% major complication rate. After a mean follow-up period of 56.6 months 96% of patients had achieved a complete response. Esophagectomy for failed endotherapy was necessary in only 12 patients (3.7%). Metachronous lesions or local recurrence developed in 140 patients (14.5%), but was successfully retreated endoscopically in 79% of patients. The calculated 10-year overall survival was 75%, and only two patients died from esophageal adenocarcinoma. These excellent results should make endoscopic therapy the preferred therapy for intramucosal adenocarcinoma in appropriate patients. Risk factors for failure of endoscopic therapy are still being identified, but include ultra-long segment (>8 cm) Barrett's, poorly controlled reflux disease, and high-grade tumor differentiation. Tumors associated with an increased risk for lymph node metastases include those with lymphovascular invasion, size >2 cm, and invasion into the submucosa.

Treatment of Gastroesophageal Reflux Disease

Medical Treatment

GERD is one of the most prevalent conditions encountered in general medical practice. As a result, medications for control of GERD comprise one of the largest pharmaceutical markets in the United States and abroad. Since PPIs were introduced in the United States in 1989, a number of different agents have emerged, each with substantial penetration in the marketplace. Data from the year 2004 reveal that, of the top 10 expenditures for medications in the United States, the third highest dollar amount was spent on Prevacid (lansoprazole, TAP Pharmaceutical Products, Inc., Lake Forest, Illinois; \$4.0 billion), while the fourth highest was on Nexium (esomeprazole magnesium, AstraZeneca Pharmaceuticals, Wilmington, Delaware; \$3.6 billion).^{152,153}

GERD is such a common condition that most patients with mild symptoms carry out self-medication, particularly now that generic and over-the-counter H₂-receptor antagonists (H₂RAs) and PPIs have become widely available. When first seen with symptoms of heartburn or regurgitation without obvious complications, patients can reasonably be placed on 8 to 12 weeks of acid suppression therapy before extensive investigations are carried out. In many situations, symptoms successfully resolve. Patients should be advised to elevate the head of the bed; avoid tight clothing; eat small, frequent meals; avoid eating their nighttime meal shortly before retiring; lose weight; and avoid alcohol, coffee, chocolate, and peppermints, which may aggravate the symptoms. Medications to promote gastric emptying, such as metoclopramide, are beneficial in early disease but of little value in more severe disease.

The mainstay of maintenance medical therapy is acid suppression. Patients with persistent symptoms should be given PPIs, such as omeprazole. In doses as high as 40 mg/day, they can effect an 80% to 90% reduction in gastric acidity. Such a regimen usually heals mild esophagitis, but healing may occur in only three-fourths of patients with severe esophagitis. It is important to realize that in patients who reflux a combination of gastric and duodenal juice, inadequate acid suppression therapy may give symptomatic improvement while still allowing mixed reflux to occur. This can result in an environment that allows persistent mucosal damage in an asymptomatic patient. Unfortunately, within 6 months of discontinuation of any form of medical therapy for GERD, 80% of patients have a recurrence of symptoms.¹⁵⁴

In patients with reflux disease, esophageal acid exposure is reduced by up to 80% with H₂RAs and up to 95% with PPIs. Despite the superiority of the latter class of drug over the former, periods of acid breakthrough still occur.^{155,156} Breakthrough occurs most commonly at nighttime and is some justification for a split rather than a single dosing regimen. Katzka et al.¹⁵⁵ studied 45 patients with breakthrough reflux symptoms while on omeprazole 20 mg b.i.d. and found that 36 patients were still refluxing, defined by a total distal esophageal acid exposure greater than 1.6%. Peghini et al.¹⁵⁶ employed intragastric pH monitoring in 28 healthy volunteers and 17 patients with reflux disease and found that nocturnal recovery of acid secretion (more than 1 hour) occurred in 75% of the individuals.

Recovery of acid secretion occurred within 12 hours of the oral evening dose of PPI, the median recovery time being 7.5 hours. This is particularly pertinent because it is during the nighttime and early morning that asthma symptoms are most pronounced and that peak expiratory flow rate is at its lowest. Ranitidine 300 mg at bedtime appears superior to omeprazole 20 mg at bedtime in preventing acid breakthrough, likely due to the abolition of histamine-mediated acid secretion in the fasting state.

An accumulating body of literature suggests potential adverse consequences to long-term acid suppressive therapy. A population-based cohort study from the Netherlands covering the years 1995–2002 revealed higher incidence rates of community-acquired pneumonia in patients using H₂RAs or PPIs compared to those who never used them or those who had used them previously but stopped.¹⁵⁷ The risk was most pronounced for PPIs and showed a clear dose–response relationship. Other studies have focused on the association between acid suppression and the development of osteoporosis-related fractures.^{158–160} Of note, a population-based study from the United Kingdom assessed the risk of hip fractures from long-term PPI therapy.¹⁵⁸ The study covered the years 1987–2003 and compared users of PPI therapy to nonusers of any acid suppressive medication. The risk of hip fracture was significantly increased in patients prescribed long-term high-dose PPI, and the strength of the association increased with increasing duration of PPI therapy. The authors conjectured that calcium malabsorption secondary to chronic acid suppression may potentially explain the positive association. Other concerning side effects of PPI use have surfaced and include interactions with antiplatelet medications and a recent association with an increased risk for acute myocardial infarction.

Failure of acid suppression to control symptoms or immediate return of symptoms after stopping treatment suggests that either the diagnosis is incorrect or the patient has relatively severe disease. Endoscopic examination at this stage of the patient's evaluation provides the opportunity for assessing the severity of mucosal damage and the presence of Barrett esophagus. Both of these findings on initial endoscopy predict a high risk for medical failure. A measurement of the degree and pattern of esophageal exposure to gastric juice, with 24-hour pH monitoring, should be obtained at this point. The status of the LES and the function of the esophageal body should also be assessed. These studies identify features that predict a poor response to medical therapy, frequent relapses, and the development of complications and include supine reflux, poor esophageal contractility, erosive esophagitis, a CLE, and a structurally defective sphincter. Patients who have these risk factors should be given the option of surgery as a primary therapy with the expectation of long-term control of symptoms and complications.

Antireflux Surgery

Indications. Antireflux surgery is indicated for the treatment of objectively documented, relatively severe GERD. Candidates for surgery include not only patients with erosive esophagitis, stricture, and Barrett esophagus but also those without severe mucosal injury who are dependent on PPIs for symptom relief. Patients with atypical or RSs who have a good response to intensive medical treatment are also candidates. The option of antireflux surgery should be given to all patients who have demonstrated the need for long-term medical therapy, particularly if escalating doses of PPIs are needed to control symptoms. Antireflux surgery may be the preferred option in patients younger than 50 years, those who are noncompliant with their drug regimen, those for whom medications are a financial burden, and those who favor a single intervention over long-term drug treatment. It may be the treatment of choice in patients who are at high risk of progression despite medical therapy. Although this population is not well defined, risk factors that predict progressive disease and a poor response to medical therapy include (a) nocturnal reflux on 24-hour esophageal pH study, (b) a structurally deficient LES, (c) mixed reflux of gastric and duodenal juice, and (d) mucosal injury at presentation.¹⁶¹

Preoperative Evaluation. Successful antireflux surgery is largely defined by two objectives: the achievement of long-term relief of reflux symptoms and the absence of complications or complaints after the operation. In practice, achieving these two deceptively simple goals is difficult. Both are critically dependent on establishing that the symptoms for which the operation is performed are the result of excess esophageal exposure to gastric juice, as well as the proper performance of the appropriate antireflux procedure. Success can be expected in the vast majority of patients if these two criteria are met. The status of the LES is not as important a factor as in the days of open surgery. Patients with normal resting sphincters are often selected for antireflux surgery in the era of laparoscopic fundoplication. The outcome is not dependent on sphincter function. There are four important goals of the diagnostic approach to patients suspected of having GERD and being considered for antireflux surgery (Table 42-3).

Table 42-3 Goals of the Diagnostic Approach to Patients Suspected of Having GERD and Being Considered for Antireflux Surgery

Establish that GERD is the underlying cause of the patient's symptoms.
Estimate the risk of progressive disease.
Determine the presence or absence of esophageal shortening.
Evaluate esophageal body function and, occasionally, gastric emptying function.

GERD, gastroesophageal reflux disease.

The introduction of laparoscopic access, coupled with the growing recognition that surgery is a safe and durable treatment for GERD, has dramatically increased the number of patients being referred for laparoscopic fundoplication compared to the prelaparoscopic era. Recent data suggest that the peak use of antireflux surgery in the United States occurred in 1999, with an estimated 15.7 cases per 100,000 adults at that time.¹⁶² Since then, the frequency of antireflux surgery has declined, such that an estimated 11 antireflux procedures were performed per 100,000 adults in 2003. This recent decline may reflect the availability of generic and over-the-counter PPIs, a constantly evolving menu of endoscopic antireflux therapies, increased utilization of Roux-en-Y gastric bypass for control of GERD in morbidly obese individuals, and the long-term efficacy of fundoplication being called into question. Given the various therapies for GERD, each with its potential advantages and shortcomings, accurate and contemporary data regarding outcomes after antireflux surgery are necessary as a basis against which other established and novel therapies must be judged.

Given the large number of surgical referrals, the importance of selecting patients for surgery who are likely to have a successful outcome cannot be overemphasized. Although a Nissen fundoplication will reliably and reproducibly halt the return of gastroduodenal juice into the esophagus, little benefit is likely if the patient's symptoms are not caused by this specific pathophysiologic derangement. Thus, in large part, the anticipated success rate of laparoscopic fundoplication is directly proportional to the degree of certainty that GERD is the underlying cause of the patient's complaints.

Table 42-4 Predictors of Outcome after Laparoscopic Fundoplication: Stepwise Logistic Regression Results of 199 Patients

Predictor	Status	Adjusted Odds Ratio (95% Confidence Intervals)	Wald's <i>p</i> Value
Composite acid score	Increased	5.4 (1.9–15.3)	<0.001
	Normal	—	—
Symptom	Typical	5.1 (1.9–13.7)	<0.001
	Atypical	—	—
Response to medical therapy	Complete/partial	3.3 (1.3–8.7)	0.02
	Minor/none	—	—

Odds ratios and corresponding *p* values are adjusted for age and for all other factors in the model. From Campos GMR, Peters JH, DeMeester TR, et al. Multivariate analysis of the factors predicting outcome after laparoscopic Nissen fundoplication. *J Gastrointest Surg* 1999;3:292–300.

Three factors predictive of a successful outcome following antireflux surgery have emerged (Table 42-4).¹⁶³ These are (a) an abnormal score on 24-hour esophageal pH monitoring; (b) the presence of typical symptoms of GERD, namely, heartburn or regurgitation; and (c) symptomatic improvement in response to acid suppression therapy prior to surgery. It is immediately evident that each of these factors helps to establish that GERD is indeed the cause of the patient's symptoms and that they have little to do with the severity of the disease.

Endoscopic Assessment. Endoscopic visualization of the esophagus equates to the physical examination of the foregut and is a critical part of the preoperative evaluation of patients with GERD. Its main aim is to detect complications of GE reflux, the presence of which may influence therapeutic decisions.

In every patient, the locations of the diaphragmatic crura, the GE junction, and the squamocolumnar junction are determined. These anatomic landmarks are commonly at three different sites in patients with GERD. The crura are usually evident and can be confirmed by having the patient sniff during the

examination. The anatomic GE junction is identified as the point where the gastric rugal folds meet the tubular esophagus and is often below the squamocolumnar junction, even in patients without otherwise obvious Barrett esophagus.

Endoscopic esophagitis is defined by the presence of mucosal erosions (Table 42-5). When present, the grade and length of esophageal mucosal injury are recorded. The presence and length of columnar epithelium extending above the anatomic GE junction is also noted. CLE is suspected at endoscopy when there is difficulty in visualizing the squamocolumnar junction at its normal location and by the appearance of a velvety red luxuriant mucosa. The presence of Barrett esophagus is confirmed by biopsy evidence of specialized intestinal metaplasia involving the tubular esophagus and is considered histologic evidence of GERD. Endoscopic visualization of columnar lining without histologic confirmation of specialized intestinal metaplasia is not considered Barrett esophagus and likely has no premalignant potential. Multiple biopsies should be taken in a cephalad direction to determine the level at which the junction of Barrett epithelium and normal squamous mucosa occurs. Barrett esophagus is susceptible to ulceration, bleeding, stricture formation, and malignant degeneration. Dysplasia is the earliest sign of malignant change. Because dysplastic changes typically occur in a random distribution within the distal esophagus, a minimum of four biopsies (each quadrant) every 2 cm should be obtained from the metaplastic epithelium. Particular attention must be paid to the squamocolumnar junction in these patients, where a mass, ulcer, nodularity, or inflammatory tissue is always considered suspicious for malignancy and requires thorough biopsy or ER. The GE junction is defined endoscopically where the tubular esophagus meets gastric rugal folds, and the squamocolumnar junction is where there is an obvious change from the velvety and darker columnar epithelium to the lighter squamous epithelium.

CLASSIFICATION

Table 42-5 Modified Los Angeles Classification of Esophagitis

Grade	Lesion
A	One (or more) mucosal break of longer than 5 mm that does not extend between the tops of two mucosal folds
B	One (or more) mucosal break more than 5 mm long that does not extend between the tops of two mucosal folds
C	One (or more) mucosal break that is continuous between the tops of two or more mucosal folds but that involves <75% of the circumference
D	One (or more) mucosal break that involves at least 75% of the esophageal circumference

After completion of the esophageal examination, the first and second portions of the duodenum and the stomach are systematically inspected. This is commonly done on withdrawal of the endoscope. When the antrum is visualized, the incisura angularis appears as a constant ridge on the lesser curve. Turning the lens of the scope 180 degrees allows inspection of the fundus and cardia. Attention is paid to the frenulum (angle of His) of the esophagogastric junction and to the closeness with which the cardia grips the scope. Hill et al.⁸⁷ have graded the appearance of this valve on a scale from I to IV according to the degree of unfolding or deterioration of the normal valve architecture. This grading system has been correlated with the presence of increased esophageal acid exposure, occurring predominantly in patients with a grade III or IV valve.

A hiatal hernia is endoscopically confirmed by finding a pouch lined with gastric rugal folds lying 2 cm or more above the margins of the diaphragmatic crura. A prominent sliding hernia is frequently associated with increased esophageal exposure to gastric juice. When a PEH exists, particular attention is given to exclude a gastric ulcer or gastritis within the pouch. The term *Cameron erosions* refers to such mucosal erosions occurring in large sliding or PEHs, typically at the level of the diaphragmatic hiatus. The intragastric retroflex or “J” maneuver is important in evaluating the full circumference of the mucosal lining of the herniated stomach. As the endoscope is removed, the esophagus is again examined and biopsies taken. The location of the cricopharyngeus is identified and the larynx and vocal cords are visualized. Acid reflux may result in inflammation of the larynx. Vocal cord movement is recorded both as a reference for subsequent surgery and an assessment of the patient’s ability to protect the airway.

Twenty-Four Hour Ambulatory pH Monitoring. The most direct method of assessing the relationship between symptoms and GERD is to measure the esophageal exposure to gastric juice with an indwelling

pH electrode. Miller¹⁶⁴ first reported prolonged esophageal pH monitoring in 1964, although it was not until 1973 that its clinical applicability and advantages were demonstrated by Johnson and DeMeester.¹⁶⁵ Ambulatory pH testing is considered by many to be the “gold standard” for the diagnosis of GERD, because it has the highest sensitivity and specificity of all tests currently available. Some experts have suggested that 24-hour pH monitoring be used selectively, limited to patients with atypical symptoms or no endoscopic evidence of GE reflux. Given present-day referral patterns, more than half of the patients referred for antireflux surgery will have no endoscopic evidence of mucosal injury. For these patients, 24-hour pH monitoring provides the only objective measure of the presence of pathologic esophageal acid exposure. Although it is true that most patients with typical symptoms and erosive esophagitis have a positive 24-hour pH result, the pH study provides other useful information. It quantifies the actual time that the esophageal mucosa is exposed to gastric juice, measures the ability of the esophagus to clear refluxed acid, and correlates esophageal acid exposure with the patient’s symptoms. It is the only way to quantitatively express the overall degree and pattern of esophageal acid exposure, both of which may impact the decision toward surgery.¹⁶⁶ Patients with nocturnal or bipositional reflux have a higher prevalence of complications and failure of long-term medical control. For these reasons, we continue to advocate the routine use of pH monitoring in clinical practice.

Table 42-6 Normal Values for Esophageal Exposure to pH <4 in 50 Subjects

Component	Mean	Standard Deviation	95th Percentile
Total time pH <4	1.51	1.36	4.45
Upright time pH <4	2.34	2.34	8.42
Supine time pH <4	0.63	1.0	3.45
No. episodes	19.00	12.76	46.9
No. >5 min	0.84	1.18	3.45
Longest episode	6.74	7.85	19.8

From Johnson LF, DeMeester TR. Development of the 24-hour intraesophageal pH monitoring composite scoring system. *J Clin Gastroenterol* 1986;8(suppl 1):52–58.

Present technology includes both transnasal catheter-based pH probes and an implantable capsule (Bravo pH system, Medtronic Corporation, Minneapolis, Minnesota) placed under endoscopic guidance.^{166–168} The units used to express esophageal exposure to gastric juice are (a) cumulative time the esophageal pH is below a chosen threshold, expressed as the percent of the total, upright, and supine monitored time; (b) frequency of reflux episodes above a chosen threshold, expressed as number of episodes per 24 hours; and (c) duration of the episodes, expressed as the number of episodes greater than 5 minutes per 24 hours and the time in minutes of the longest episode recorded. Table 42-6 shows the normal values for these components of the 24-hour record at the whole number pH threshold derived from 50 normal, asymptomatic subjects. The upper limits of normal were established at the 95th percentile. Most centers use pH 4 as the threshold. Combining the result of the six components into one expression that reflects the overall esophageal acid exposure below a pH threshold, a pH score was calculated by using the standard deviation of the mean of each of the six components measured.

Several limitations exist, however, to standard pH monitoring: nonacid reflux events are not detected, the height and quantity of refluxate above the gastroesophageal junction are not defined, and the physical nature of the refluxed material (i.e., liquid, gas, or a mixture) cannot be differentiated. As reflux symptoms such as regurgitation and cough may be present in the absence of demonstrable reflux of acid, improved modalities for detection of nonacid refluxate may be clinically important.

Ambulatory Combined Impedance–pH Monitoring. New technology has been introduced into clinical practice that allows for detection of both acid and nonacid refluxate. The Sleuth system (Sandhill Scientific, Denver, Colorado) combines pH monitoring and intraluminal impedance measurements using a single catheter (Fig. 42-34). The technology identifies refluxate via changes in impedance caused by the presence of a bolus in the esophagus, and the reflux event can be categorized as acid or nonacid by the contemporaneous change in intraluminal pH. Multichannel intraluminal impedance (MII) has been validated as an appropriate method for the evaluation of gastrointestinal function and reflux.¹⁶⁹ All episodes of gastroesophageal reflux can be detected using this technology without regard to their chemical composition. Surprisingly, recent studies using this technology have shown that, in normal subjects, PPI therapy does not alter the number of reflux episodes; it simply converts them to neutral pH.¹⁷⁰ This observation may have important implications in the treatment of GERD.

Figure 42-34. Combined multichannel intraluminal impedance-pH catheter. (Reproduced with permission from Mainie I, Tutuian R, Agrawal A, et al. Combined multichannel intraluminal impedance-pH monitoring to select patients with persistent gastro-oesophageal reflux for laparoscopic Nissen fundoplication. *Br J Surg* 2006;93:1483–1487.)

Combined MII-pH monitoring has recently been used to select patients, both with typical and atypical manifestations of GERD and who are resistant to medical treatment, for fundoplication.¹⁷¹ Patients with a positive symptom index, as assessed by combined MII-pH testing while on PPI therapy, were noted to respond well to surgery. Another recent trial demonstrated that combined MII-pH testing is more accurate for the preoperative assessment of GERD in patients off of PPI therapy compared to pH monitoring alone.¹⁷²

Assessment of Esophageal Length. Esophageal shortening is a consequence of scarring and fibrosis associated with repetitive esophageal injury. Anatomic shortening of the esophagus can compromise the ability to perform an adequate tension-free fundoplication and may result in an increased incidence of breakdown or thoracic displacement of the repair. Esophageal length is best assessed preoperatively using video roentgenographic contrast studies and endoscopic findings. Endoscopically, hernia size is measured as the difference between the diaphragmatic crura, identified by having the patient sniff, and the GE junction, identified as the loss of gastric rugal folds. We consider the possibility of a short esophagus in patients with strictures or those with large hiatal hernias (>5 cm), particularly when the latter fail to reduce in the upright position on a video barium esophagram.¹⁷³

The definitive determination of esophageal shortening is made intraoperatively when, after thorough mobilization of the esophagus, the GE junction cannot be reduced below the diaphragmatic hiatus without undue tension on the esophageal body. Surgeons performing fundoplication have reported varying incidences of esophageal shortening, attesting to the judgment inherent in defining and recognizing “undue tension.” An advantage of transthoracic fundoplication is the ability to mobilize the esophagus extensively from the diaphragmatic hiatus to the aortic arch. With the GE junction marked with a suture, esophageal shortening is defined by an inability to position the repair beneath the diaphragm without tension. In this situation, a Collis gastroplasty coupled with either a partial or complete fundoplication may be performed.¹⁷⁴

Potential pitfalls of laparoscopic fundoplication include the elevation of the diaphragm due to pneumoperitoneum, potentially contributing to a false impression that esophageal length is adequate, and the limited ability to mobilize the esophagus relative to the transthoracic approach.¹⁷⁵ In our experience, the failure to appreciate esophageal shortening is a major cause of fundoplication failure and is often the explanation for the “slipped” Nissen fundoplication. In many such instances, the initial repair is incorrectly constructed around the proximal tubularized stomach rather than the terminal esophagus. Surgeons opting to perform fundoplication laparoscopically in the setting of potential esophageal shortening must be vigilant of esophageal tension, technically facile at extensive mediastinal mobilization of the esophagus while preserving vagal integrity, and able to perform a laparoscopic or open transabdominal Collis gastroplasty should esophageal lengthening be necessary.

Radiographic Evaluation. Radiographic assessment of the anatomy and function of the esophagus and stomach is one of the most important parts of the preoperative evaluation. Critical issues are assessed, including the presence of esophageal shortening (Fig. 42-35), the size and reducibility of a hiatal hernia, and the propulsive function of the esophagus for both liquids and solids.

The definition of radiographic GE reflux varies depending on whether reflux is spontaneous or

induced by various maneuvers. In only about 40% of patients with classic symptoms of GERD is spontaneous reflux observed by the radiologist (i.e., reflux of barium from the stomach into the esophagus with the patient in the upright position). In most patients who show spontaneous reflux on radiography, the diagnosis of increased esophageal acid exposure is confirmed by 24-hour esophageal pH monitoring. Therefore, the radiographic demonstration of spontaneous regurgitation of barium into the esophagus in the upright position is a reliable indicator that reflux is present. On the contrary, failure to see radiographic reflux does not prove the absence of reflux disease.

Figure 42-35. Barium-filled esophagogastric segment in a patient with a short esophagus. Note that the gastroesophageal junction is well above the hiatus.

DIAGNOSIS

Table 42-7 University of Southern California Protocol for Video Esophagram Studies

Patient Position	Purpose	Technique
Prone RAO	Esophageal body function	Five separate 10-mL swallows, 15 s between each, follow bolus on videotape Video swallow over thoracic inlet and another over distal third of esophagus without panning
	Esophageal diameter	Rapid swallow of several gulps to distend esophagus maximally
	Gastric function	Video-record activity of stomach and duodenum for 30 s in prone position
Supine	Relationship of GE junction to hiatus	Two or three individual swallows focused on distal esophagus and GE junction
Erect	Cricopharyngeal function	Lateral and anteroposterior views of oropharynx and upper esophagus
	Mucosal injury	Spot of collapsed esophagus for mucosal detail
	Reducibility of hernia	Video images of one or two swallows focused on distal esophagus and GE junction
	Gas distention of distal esophagus	
Erect	Solid bolus transport	Record video images of passage of two contrast-coated hamburger boluses from oropharynx to stomach

GE, gastroesophageal; RAO, right anterior oblique.

A carefully performed video esophagram can provide an enormous amount of information on the structure and function of the esophagus and stomach. The modern barium swallow emphasizes motion recording (video), utilizes a tightly controlled examination protocol (Table 42-7), and requires an understanding of esophageal physiology.

Videotaping the study greatly aids the evaluation, providing the surgeon with a real-time assessment of swallowing function, bolus transport, and the size and reducibility of an associated hiatal hernia. Given routine review before antireflux surgery, the value of the study becomes increasingly clear. The examination provides structural information including the presence of obstructing lesions and anatomic

abnormalities of the foregut. A hiatal hernia is present in more than 80% of patients with GE reflux and is best demonstrated with the patient in the prone position, which causes increased abdominal pressure and promotes distention of the hernia above the diaphragm. The presence of a hiatal hernia is an important component of the underlying pathophysiology of GE reflux. Other relevant findings include a large (>5 cm) or irreducible hernia, suggesting the presence of a shortened esophagus; a tight crural “collar” that inhibits barium transit into the stomach, suggesting a possible cause of dysphagia; and the presence of a PEH.

Lower esophageal narrowing resulting from a ring, stricture, or obstructing lesion is optimally viewed with full distention of the esophagogastric region. A full-column technique with distention of the esophageal wall can be used to discern extrinsic compression of the esophagus. Mucosal relief or double-contrast films should be obtained to enhance the detection of small esophageal neoplasms, mild esophagitis, and esophageal varices. The pharynx and UES are evaluated in the upright position, and an assessment of the relative timing and coordination of pharyngeal transit is possible.

The assessment of peristalsis on video esophagram often adds to, or complements, the information obtained by esophageal motility studies. This is in part because the video barium study can be done both upright and supine and with liquid and solid bolus material, which is not true of a stationary motility examination. This is particularly true with subtle motility abnormalities. During normal swallowing, a stripping wave (primary peristalsis) is generated that completely clears the bolus. Residual material can stimulate a secondary peristaltic wave, but usually a second pharyngeal swallow is required. Motility disorders with disorganized or simultaneous esophageal contractions have “tertiary waves” and provide a segmented appearance to the barium column, often referred to as beading or corkscrewing. In dysphagic patients, a barium-impregnated marshmallow, bread, or hamburger is a useful adjunct, which can discern a functional esophageal transport disturbance not evident on the liquid barium study. Reflux is not easily seen on video esophagram, and motility disorders that cause retrograde barium transport may be mistaken for reflux.

Assessment of the stomach and duodenum during the barium study is a necessity for proper preoperative evaluation of the patient with GERD. Evidence of gastric or duodenal ulcer, neoplasm, or poor gastroduodenal transit has obvious importance in the proper preoperative evaluation.

Assessment of Esophageal Function. The presence of poor esophageal body function can impact the likelihood of relief of regurgitation, dysphagia, and RSs following surgery and may influence the decision to undertake a partial rather than a complete fundoplication. When peristalsis is absent or severely disordered, many surgeons would opt for a partial fundoplication, although recent studies would suggest a complete fundoplication may be appropriate even in this setting. The less favorable response of atypical, compared with typical, reflux symptoms after fundoplication may be related to persistent poor esophageal propulsive function and the continued regurgitation of esophageal contents.^{176,177}

The function of the esophageal body is assessed with esophageal manometry. Conventional water-perfused or solid-state manometry is performed with five pressure transducers located in the esophagus (Fig. 42-36). To standardize the procedure, the most proximal pressure transducer is located 1 cm below the well-defined cricopharyngeal sphincter. With this method, a pressure response along the entire esophagus can be obtained during one swallow. The study consists of recording 10 wet swallows with 5 mL of water. Amplitude, duration, and morphology of contractions following each swallow are all calculated at the five discrete levels within the esophageal body (Fig. 42-37). The delay between onset or peak of esophageal contractions at the various levels of the esophagus is used to calculate the speed of wave propagation and represents the degree of peristaltic activity.

Figure 42-36. Illustration of the position of a five-channel esophageal motility catheter during the esophageal body portion of the study.

Recently, HRM (ManoScan360, Sierra Scientific Instruments, Los Angeles, CA) has been introduced into clinical practice and may possess several advantages over the other manometric systems currently available.¹⁷⁸ The high-resolution catheter is 4.2 mm in diameter and has 36 solid-state transducers spaced at 1-cm intervals, compared to the standard 3- to 5-cm spacing of traditional water-perfused or solid-state catheters. Pressure transduction technology allows each of the sensors to detect pressure over a length of 2.5 mm in 12 radially dispersed sectors. The pressure of each sector is averaged, making each of the 36 sensors a circumferential pressure detector. This construct allows a more thorough and precise evaluation of esophageal function than standard manometry. In addition, given the number and span of transducers across the length of the catheter, the UES, esophageal body, and lower esophageal sphincter can be assessed simultaneously without moving the catheter. Thus, the study can be performed more quickly and with improved patient comfort compared to conventional manometry in that multiple repositionings of the catheter are not required to complete the evaluation. The experience in our laboratory has been that HRM takes, on average, only 8.1 minutes to complete, whereas standard manometry with a solid-state catheter takes 24.4 minutes ($p < 0.0001$).¹⁴¹ Finally, the color-coded readouts allow for a better, more intuitive, graphic description of the motor activity of the esophagus, the characteristics of the lower esophageal sphincter, and the presence of a hiatal hernia compared to the other technologies (Fig. 42-38). The catheter, however, is expensive with a high replacement cost should it break. With increasing experience and further study, the pros and cons of this new technology will continue to be elucidated.

Assessment of Gastric Function. Esophageal disorders are frequently associated with abnormalities of duodenogastric function. Symptoms suggestive of gastroduodenal pathology include nausea, epigastric pain, anorexia, and early satiety. Abnormalities of gastric motility or increased gastric acid secretion can be responsible for increased esophageal exposure to gastric juice. If not identified before surgery, unrecognized gastric motility abnormalities are occasionally “unmasked” by an antireflux procedure, resulting in disabling postoperative symptoms.⁴³ Considerable experience and judgment are necessary to identify the patient with occult gastroduodenal dysfunction. The surgeon should maintain a keen awareness of this possibility and investigate the stomach given any suggestion of problems. Tests of duodenogastric function that are helpful when investigating the patient with GE reflux include gastric emptying studies, gastric acid analysis, 24-hour gastric pH monitoring, and ambulatory bilirubin monitoring of the esophagus and stomach.

Figure 42-37. Computer-generated graphic representation of esophageal body contraction amplitudes, duration of contraction, and wave progression.

Figure 42-38. High-resolution manometry (HRM) display. Note the color-coded graphic description of esophageal body wave amplitudes and lower esophageal sphincter function.

Poor gastric emptying or transit can provide for reflux of gastric contents into the distal esophagus. Standard gastric emptying studies are performed with radionuclide-labeled meals. They are often poorly standardized and difficult to interpret. Emptying of solids and liquids can be assessed simultaneously when both phases are marked with different tracers. After ingestion of a labeled standard meal, gamma camera images of the stomach are obtained at 5- to 15-minute intervals for 1.5 to 2 hours. After correction for decay, the counts in the gastric area are plotted as percentage of total counts at the start of the imaging. The resulting emptying curve can be compared with data obtained in normal volunteers. In general, normal subjects will empty 59% of a meal within 90 minutes.

Evolving Technologies for Assessment of Extraesophageal Manifestations of GERD. Given the difficulty inherent in proving that GERD is etiologic to extraesophageal symptoms, such as cough, sore throat, or hoarseness, or to more chronic and insidious conditions, such as repetitive aspiration or pulmonary fibrosis, a great interest exists to develop testing modalities that are both more sensitive and more specific than the technologies widely utilized at present. Several recent testing paradigms have emerged that appear promising, despite lacking extensive data.

Simultaneous 24-hour MII-pH and continuous pulse oximetry recently was evaluated in 20 subjects with primary RSs and 10 with primary ESs.¹⁷⁹ Oxygen saturation monitoring was performed using a finger clip probe (Pulsox-300i, Konica Minolta Sensing, Inc., Ramsey, NJ) that measures the arterial oxygen saturation (SpO₂) and pulse rate every second via standard photometrics (Fig. 42-39). An oxygen desaturation event was defined by either (a) SpO₂ less than 90% or (b) SpO₂ drop of 6% or greater (Fig. 42-40). Reflux events, both acid and nonacid, were temporally correlated to desaturation events. Markedly more reflux events were associated with desaturation in patients with RSs (74.5%, 832/1,117 reflux events) than in patients with ESs (30.4%, 223/734 reflux events, $p < 0.0001$) (Fig. 42-41). In addition, the difference in reflux desaturation association was more pronounced with

proximal reflux (80.3% with RSs vs. 20.4% with ESs, $p < 0.0001$). While a number of issues still need to be resolved with this technique for it to be considered reliable and useful, the observation of oxygen desaturations in temporal proximity to reflux events, particularly in patients with RSs, is intriguing and may prove meaningful.

A pharyngeal pH catheter (Restech, San Diego, CA) also was recently developed and consists of a thin (1.5-mm diameter) nasally passed catheter that can be positioned in the pharynx with the assistance of a light-emitting diode (LED) mounted on the tip. The catheter, being small, is well tolerated and measures both liquid and aerosolized reflux events. Optimal pH thresholds are currently being evaluated to predict the responsiveness of extraesophageal symptoms to antireflux therapy, either medical or surgical.

Finally, several centers have investigated the utility of salivary/sputum or laryngoscopic biopsy specimen assays for pepsin as a marker for underlying GERD.^{180–182} As pepsin is produced only in the gastric mucosa, its presence in the sputum or larynx reflects gastric reflux. Pepsin assays, when compared to ambulatory pH monitoring, showed a high correlation to proximal reflux events. Positive assays were also highly correlated with the presence of LPR symptoms. Still lacking are data showing that a positive sputum or laryngeal pepsin assay predicts a successful symptomatic response to antireflux therapy. With additional study, the utility and reliability of each of these modalities will be determined in the clinical marketplace.

Partial Versus Complete Fundoplication. The decision between partial and complete fundoplication and an open or laparoscopic approach requires considerable judgment. Two randomized studies of unselected patients undergoing laparoscopic fundoplication have shown equivalence of complete and partial fundoplications, anterior in one study¹⁸³ and posterior in the other,⁸³ in terms of operative time, perioperative morbidity, and hospital stay. Watson et al.¹⁸³ noted that resting and residual LES pressures were greater after complete fundoplication and that esophageal clearance of liquid radioisotope was prolonged in these patients compared with after partial fundoplication. Six months after operation, partial fundoplication was linked to a greater overall level of patient satisfaction manifested by a lower incidence of the symptoms of dysphagia, inability to belch, and excessive flatus. Laws et al.¹⁸⁴ did not identify any difference in symptomatic outcome between patients treated by complete and those treated by posterior partial fundoplication at a mean follow-up time of 27 months.

Figure 42-39. Pulsox-300i with finger probe used to assess ambulatory oxygen saturation (Konica Minolta Sensing, Inc.).

Figure 42-40. Example of the association between a reflux episode detected by multichannel intraluminal impedance–pH study and oxygen desaturation detected by pulse oximetry. (Reproduced with permission from Salvador R, Watson TJ, Herbella F, et al. Association of gastroesophageal reflux and O₂ desaturation: a novel study of simultaneous 24-h MII-pH and continuous pulse oximetry. *J Gastrointest Surg* 2009;13:854–861.)

Hagedorn et al.¹⁸⁵ reported on the results of a randomized, controlled trial comparing total (Nissen-Rossetti) and posterior partial (Toupet) fundoplication in which long-term efficacy was assessed. A total of 110 patients (54 undergoing a total wrap, 56 a partial wrap) completed a median follow-up of 11.5 years. No significant differences were observed between the groups in terms of heartburn, regurgitation, or dysphagia scores. A significant difference, however, was noted in the prevalence of rectal flatus and postprandial fullness, which were reported more often by those having undergone a total fundoplication.

Figure 42-41. Scatterplot of association between reflux episodes and desaturation events by patient group. The prevalence of reflux-associated desaturations was remarkably different between the two groups ($p < 0.0001$). (Reproduced with permission from Salvador R, Watson TJ, Herbella F, et al. Association of gastroesophageal reflux and O₂ desaturation: a novel study of simultaneous 24-h MII-pH and continuous pulse oximetry. *J Gastrointest Surg* 2009;13:854–861.)

A recent prospective, randomized trial from Australia comparing laparoscopic Nissen fundoplication to an anterior 180-degree partial fundoplication similarly revealed no significant differences between the two groups with regard to reflux symptoms, dysphagia, abdominal bloating, ability to belch, and overall satisfaction at 10 years' follow-up.¹⁸⁶

These observations, however, must be tempered by reports questioning the durability of partial fundoplications. Jobe et al.¹⁸⁷ found that 51% of patients studied by 24-hour esophageal pH monitoring after Toupet fundoplication still had pathologic acid exposure. Disturbingly, only 40% of the refluxers were symptomatic. Two studies have identified the presence of a defective LES function, an aperistaltic distal esophagus, and higher grades of esophagitis (Savary-Miller grades 2 to 4) as risk factors for partial fundoplication failure.^{185,187} Bell et al.¹⁸⁸ reported recurrent reflux in 14% after Toupet fundoplication. The presence of mild esophagitis and a normal LES were associated with a 3-year success rate of 96%, whereas the presence of complicated esophagitis or a defective LES lowered this value to 50% (Fig. 42-35).

These findings highlight an apparent paradox, in that partial fundoplications afford suboptimal reflux protection in those most at risk from the effects of unabated GERD. The question arises, therefore, whether total fundoplication should be applied more liberally to patients with severe reflux disease and associated esophageal dysmotility. Patti et al. recently reported on 357 patients undergoing antireflux surgery, 235 undergoing a “tailored approach” with either a partial or total fundoplication depending on the results of preoperative manometry, and 122 more recent patients undergoing a total fundoplication regardless of the quality of esophageal peristalsis.¹⁸⁹ In the first group, heartburn from pathologic reflux, confirmed by postoperative ambulatory esophageal pH monitoring, recurred in 19% after partial fundoplication and in 4% after total fundoplication. In the latter group, heartburn recurred in 4% after total fundoplication. Importantly, the incidence of postoperative dysphagia was similar in the two groups. This recent evidence, as well as our own experience, has led us to utilize the complete fundoplication more readily, particularly in patients with Barrett esophagus. Currently, partial fundoplication is best reserved for patients with severe esophageal dysmotility approaching aperistalsis,

such as occurs in scleroderma, or in combination with a distal esophageal myotomy for achalasia.¹⁹⁰

Laparoscopic Nissen Fundoplication. The performance of laparoscopic fundoplication should include the steps identified in [Table 42-8](#).

MANAGEMENT

Table 42-8 Elements of Laparoscopic Fundoplication

1. Crural dissection, identification and preservation of both vagi including the hepatic branch of the anterior vagus
2. Circumferential dissection of the esophagus
3. Crural closure
4. Fundic mobilization by division of short gastric vessels
5. Creation of a short, loose fundoplication by enveloping the anterior and posterior wall of the fundus around the lower esophagus

Port Placement. Five ports are used. The camera is placed above and to the left of the umbilicus, roughly one-third of the distance to the xiphoid process. In most patients, placement of the camera in the umbilicus is too low to allow adequate visualization of the hiatal structures once dissected. A transrectus location is preferable to midline to minimize the prevalence of port site hernia formation. The liver is retracted with a Nathensen retractor placed through a 5-mm incision on the right side of the xiphoid. A retraction port is placed slightly above the level of the umbilicus, in the left anterior axillary line. Placement of these ports too far lateral or too low on the abdomen will compromise the excursion of the instruments and thus the ability to retract. The left-sided operating port (surgeon’s right hand) is placed 1 to 2 cm below the costal margin approximately at the lateral rectus border. Such placement allows triangulation between the camera and the two instruments and avoids the difficulty associated with the instruments being in direct line with the camera. The right-sided operating port (surgeon’s left hand) is placed last, after the left lateral segment of the liver has been retracted. This placement prevents “sword fighting” between the liver retractor and the left-handed instrument. The falciform ligament hangs low in many patients and provides a barrier around which the left-handed instrument must be manipulated.

Hiatal Dissection. In patients without a large or PEH dissection begins with division of the gastrohepatic omentum and identification of the right crus of the diaphragm. Alternatively, when a PEH is present sac excision is started at the 2 o’clock position at the hiatus to avoid injuring the left gastric vessels which are routinely up in the chest on the right side of the hiatus.

Crural Dissection. A large left hepatic artery arising from the left gastric artery is present in up to 25% of patients ([Fig. 42-42](#)); it should be identified and can typically be divided without consequence but a pulse in the hepatoduodenal ligament should be confirmed. After incising the gastrohepatic omentum, the outside of the right crus will become evident. The peritoneum overlying the anterior aspect of the right crus is incised and the plane between the esophagus and right crus developed.

Following dissection of the right crus, attention is turned toward the phrenoesophageal ligament anteriorly. These tissues are held upward by the left-handed grasper and the esophagus and anterior vagus nerve are swept downward away from the phrenoesophageal ligament. The anterior crural tissues are then divided and the left crus identified. The anterior vagus nerve often “hugs” the left crus and can be injured in this portion of the dissection if not carefully searched for and protected. The left crus is dissected as completely as possible, including taking down the angle of His and the attachments of the fundus to the left diaphragm ([Fig. 42-43](#)). The short gastric vessels are divided along with the posterior pancreatic vessels to completely mobilize the gastric fundus. Failure to do so will result in difficulty encircling the esophagus, and increase the risk of a perforation of the posterior esophagus when developing the retroesophageal window. A window behind the GE junction can generally now be easily created and a Penrose drain passed for esophageal retraction.

Figure 42-42. Illustration of the initial dissection of the esophageal hiatus. The right crus is identified and dissected toward its posterior confluence with the left crus.

Esophageal Mobilization and Crural Closure. The esophagus is mobilized into the posterior mediastinum for several centimeters to provide maximal intra-abdominal esophageal length. Posterior and right lateral mobilization is readily accomplished. In performing the anterior and left lateral mobilization, the surgeon must take care not to injure the anterior vagus nerve. Gentle traction on the Penrose drain around the GE junction facilitates exposure. The right and left pleural reflection often come into view and should be avoided, although if a pleural opening is created it is well tolerated provided the hole is made large enough to prevent a ball-valve tension pneumothorax from developing. Continue the crural dissection to enlarge the space behind the GE junction as much as possible. Following mobilization and an assessment of intra-abdominal esophageal length, the hiatus is closed in all patients. The esophagus is held anterior and to the left and the crura approximated with two to four interrupted figure-of-eight 0-Ethibond sutures, starting just above the aortic decussation and working anterior. The authors prefer a large needle (CT1) passed down the left upper 10-mm port to facilitate a durable crural closure using absorbable pledgets in a horizontal mattress fashion. The aorta may be punctured while suturing the left crus. Identification of the anterior aortic surface and retracting the left crus via the left-handed grasper will help avoid inadvertent aortic puncture. The authors prefer extracorporeal knot tying using a “tie knot” device (LSI Solutions, Victor, New York). More recently, we have inspected the crural closure at the completion of the procedure following creation of the fundoplication and removal of the bougie. Doing so will often reveal that the bougie has dilated the hiatal opening such that a final stitch should be placed to further approximate it. Although there have been no randomized studies evaluating the role of routine crural closure, there is compelling evidence to indicate that closure should be standard. Watson et al.¹⁹¹ identified paraesophageal herniation in 17 of 253 patients (7%), the frequency being 3% in those who had undergone crural repair and 11% in those who had not.

Figure 42-43. Left-sided crural dissection. The left crus is dissected as completely as possible and the attachments of the fundus of

the stomach to the diaphragm are taken down.

Creation of the Fundoplication. A short, loose fundoplication is fashioned with particular attention to the geometry of the wrap (Fig. 42-44). The midposterior fundus is grasped and passed left to right behind the esophagus rather than pulling right to left. This ensures that the posterior fundus is used for the posterior aspect of the fundoplication. This is accomplished by placing a Babcock clamp through the left lower port and grasping the midportion of the posterior fundus (Fig. 42-45). One should gently bring the posterior fundus behind the esophagus to the right side with an upward, rightward, and clockwise twisting motion. This maneuver can be difficult, particularly for the novice. If so, placement of a 0-silk suture in the midposterior fundus 6 cm down from the GEJ and grasping it from the right side facilitates bringing the posterior fundus around to create the fundoplication. The anterior wall of the fundus is then folded over the esophagus to meet the posterior at about the 9 o'clock position such that the esophagus is imbricated within the fundus rather than having the fundus twisted or spiraled around the esophagus.

Figure 42-44. Schematic representations of the various possibilities of orientation of a Nissen fundoplication. The top set of figures represents the preferred approach, whereas the bottom two sets can be seen to result in twisting of the fundoplication.

The posterior and anterior fundic lips should be maneuvered (as in a “shoe shine”) to allow the fundus to envelope the esophagus without twisting. Laparoscopic visualization has a tendency to exaggerate the size of the posterior opening that has been dissected. Consequently, the space for the passage of the fundus behind the esophagus may be tighter than thought and the fundus relatively ischemic when brought around. If the right lip of the fundoplication has a bluish discoloration, the stomach should be returned to its original position and the posterior dissection enlarged. A 60-French bougie is passed to properly size the fundoplication, and the “lips” of the fundoplication sutured utilizing a single U-stitch of 2-0 Prolene buttressed with absorbable pledgets. The most common error is an attempt to grasp the anterior portion of the stomach to construct the right lip of the fundoplication rather than the posterior fundus. The esophagus should comfortably lie in the untwisted fundus prior to suturing. If the posterior fundus tries to pull away back under the esophagus there is tension likely from inadequate mobilization of the fundus, particularly posteriorly along the pancreas. This should be addressed to release the tension and reduce the risk of disruption of the fundoplication postoperatively. Finally, two anchoring sutures of 2-0 silk or Ethibond are placed above and below the U-stitch to complete the fundoplication. When finished, the suture line of the fundoplication should be facing in a right anterior direction (Fig. 42-46). The abdomen is then irrigated, hemostasis checked, and the Penrose drain and any sponges placed into the abdomen removed.

Figure 42-45. Placement of Babcock on the posterior fundus in preparation for passing it behind the esophagus to create the posterior or right lip of the fundoplication. Inset: To achieve the proper angle for passage, the Babcock is placed through the left lower trocar. The posterior fundus is passed left to right and grasped from the right via a Babcock through the right upper trocar. **A:** Location of posterior fundus for passage to the right side. **B:** The posterior fundus passed underneath the esophagus and grasped on the right.

Figure 42-46. Fixation of the fundoplication. The fundoplication is sutured in place with a single U-stitch of 2-0 Prolene pledgeted on the outside. A 60-French mercury-weighted bougie is passed through the gastroesophageal junction prior to fixation of the wrap to ensure a floppy fundoplication. Inset illustrates the proper orientation of the fundic wrap.

Transthoracic Nissen Fundoplication. The indications for performing an antireflux procedure by a transthoracic approach are given in [Table 42-9](#).

In the thoracic approach the hiatus is exposed through a left posterior lateral thoracotomy incision in the sixth intercostal space (i.e., over the upper border of the seventh rib). When necessary, the diaphragm is incised circumferentially 2 to 3 cm from the lateral chest wall for a distance of approximately 10 to 15 cm. The esophagus is mobilized from the level of the diaphragm to underneath the aortic arch. Mobilization up to the aortic arch is usually necessary to place the repair in a patient with a shortened esophagus into the abdomen without undue tension. Failure to do this is one of the major causes for subsequent breakdown of a repair and return of symptoms. The cardia is then freed from the diaphragm. When all the attachments between the cardia and diaphragmatic hiatus are divided, the fundus and part of the body of the stomach are drawn up through the hiatus into the chest. The vascular fat pad that lies at the GE junction is excised. Crural sutures are then placed to close the hiatus though are not tightened until later. The fundoplication is constructed by enveloping the fundus around the distal esophagus in a manner similar to that described for the abdominal approach. When complete, the fundoplication is placed into the abdomen by compressing the fundic ball with the hand and manually maneuvering it through the hiatus. The previously placed crural stitches are then tightened and knotted.

Collis Gastroplasty. In patients with a short esophagus secondary to a stricture, Barrett esophagus, or a large hiatal hernia, the esophagus is lengthened with a Collis gastroplasty. The gastroplasty lengthens the esophagus by forming a gastric tube or “neoesophagus” along the lesser curvature. The procedure allows a tension-free construction of a total or partial fundoplication around the newly formed gastric tube, with placement of the repair in the abdomen. A gastroplasty can be readily performed via either an abdominal or thoracic approach. A number of techniques have been reported for the laparoscopic performance of Collis gastroplasty, and the surgeon opting to manage the shortened esophagus laparoscopically must be able to perform such a procedure should the need arise.¹⁹² The authors prefer the wedge fundectomy technique initially described by Hunter et al. In a series of 85 patients that had a wedge fundectomy Collis gastroplasty and either a Nissen or Toupet fundoplication there were no staple line leaks or abscesses in the perioperative period, and at a median follow-up of 12 months 93% were free of heartburn. Dysphagia was significantly less common then preoperatively with new-onset dysphagia in only two patients. On upper endoscopy in 54 patients at a median of 6 months postoperatively esophagitis was only present in 11% of patients. These results suggest that a wedge fundectomy can be added safely and with good results in patients where a shortened esophagus is found intraoperatively.

INDICATIONS/CONTRAINDICATIONS

Table 42-9 Indications for Performing an Antireflux Procedure by a Transthoracic Approach

Indication	Explanation
Previous hiatal hernia repair	In this situation, a peripheral circumferential incision in the diaphragm is made to provide simultaneous exposure of the upper abdomen. This allows safe dissection of the previous repair from both the abdominal and thoracic sides of the diaphragm.
Concomitant procedure	Concomitant esophageal myotomy for achalasia or diffuse spasm.
Short esophagus	This is usually associated with a stricture or Barrett esophagus. In this situation, the thoracic approach is preferred to allow maximum mobilization of the esophagus, the performance of a Collis gastroplasty, or, if necessary, placement of the repair without tension below the diaphragm.
Sliding hiatal hernia that does not reduce below the diaphragm during a roentgenographic barium study in the upright position	This can indicate esophageal shortening and, again, a thoracic approach is preferred for maximum mobilization of the esophagus and, if necessary, the performance of a Collis gastroplasty.
Associated pulmonary pathology	The nature of the pulmonary pathology can be evaluated and the proper pulmonary surgery, in addition to the antireflux repair, can be performed.
Obesity	The abdominal repair is difficult because of poor exposure, whereas the thoracic approach gives better exposure and allows a more precise repair.

Outcomes Following Antireflux Surgery. Any discussion regarding results following fundoplication must consider:

1. Perioperative morbidity and mortality
2. Control of typical and atypical symptoms
3. Side effects
4. Objective relief from excessive esophageal acid exposure
5. Anatomic failure rates, such as recurrent hiatal herniation or slippage, and the need for reoperation

Complications of Antireflux Surgery. Carlson and Frantzides¹⁹³ reported on complications and results of primary minimally invasive antireflux operations based on a literature review. Included in their analysis were 41 papers comprising 10,489 procedures. Postoperative complications were found to occur in approximately 8% of patients, with the rate of conversion to an open procedure of about 4%. The most common perioperative complication was early wrap herniation (1.3%), defined as occurring within 48 hours of surgery. This is one complication that may be more common with the laparoscopic than open approach. The explanation for this is unclear but may be related to the opening of tissue planes by the pneumoperitoneum, the reduced tendency for adhesion formation after laparoscopic compared to open surgery, and inadequate bites of crural tissue related to the magnified view with the laparoscope. An adequate crural repair is critical in laparoscopic antireflux surgery (LARS).

Both pneumothorax and pneumomediastinum have been reported. The occurrence of pneumothorax is related to breach of either pleural membrane, usually the left, during the hiatal dissection. Chest drain insertion is usually not required because accumulated carbon dioxide rapidly dissipates following release of pneumoperitoneum by a combination of positive pressure ventilation and absorption. Tension

pneumothorax intraoperatively is typically related to a ball-valve effect from a small opening in the pleura. In this setting the laparoscopic capnoperitoneum gets into the pleural space with exhalation, but cannot escape rapidly with inhalation. Creating a large pleural defect solves this issue, and since the anesthesiologist can increase the ventilation pressure above the 15 mm used for laparoscopic pneumoperitoneum there should be no difficulty ventilating the patient adequately.

As with any laparoscopic procedure, instrumental or trocar perforation of a hollow viscera may occur. Esophageal perforation may arise intraoperatively during passage of the bougie, during the retroesophageal dissection, or as a consequence of suture pull-through. Late esophageal perforation is typically related to diathermy or dissection injury at the time of mobilization. Gastric perforations usually result from excessive traction on the fundus particularly when reducing a PEH without first mobilizing the hernia sac. Gastric perforation also occurs during reoperative fundoplication procedures. The key is to recognize the injury and repair it appropriately since generally major complications are a result of unrecognized injuries.

Hemorrhage during the course of laparoscopic fundoplication usually arises from the short gastric vessels or spleen. Rarer causes include retractor trauma to the liver, injury to the left inferior phrenic vein, an aberrant left hepatic vein, or the inferior vena cava. Cardiac tamponade as a result of right ventricular trauma has also been reported. Major vascular injury mandates immediate conversion to an open procedure to achieve hemostasis. One complication that has been virtually eliminated since the advent of laparoscopic fundoplication is incidental splenic injury necessitating splenectomy (0.06%), which occurred with a frequency of around 2% to 5% during the open era. The mortality rate for primary minimally invasive antireflux surgery has fortunately been quite low, reported at 0.08%.

Symptomatic Outcomes Following Antireflux Surgery. Studies of long-term outcome following both open and laparoscopic fundoplication document the ability of laparoscopic fundoplication to relieve typical reflux symptoms (heartburn, regurgitation, and dysphagia) in more than 90% of patients at follow-up intervals averaging 2 to 3 years and 80% to 90% of patients 5 years or more following surgery.^{35,194–201} The data include evidence-based reviews of antireflux surgery,¹⁹⁸ prospective randomized trials comparing antireflux surgery to PPI therapy¹⁹⁹ and open to laparoscopic fundoplication,²⁰⁰ and analysis of U.S. national trends in utilization and outcomes.²⁰¹ The results of laparoscopic fundoplication compare favorably with those of the “modern” era of open fundoplication. They also indicate the less predictable outcome of atypical reflux symptoms (cough, asthma, laryngitis) after surgery being relieved in only two-thirds of patients.²⁰²

A few recent trials deserve emphasis. Results were updated on a prospective, randomized trial comparing PPI therapy to antireflux surgery.²⁰³ The outcome of the study previously had been reported at a follow-up of 5 years,¹⁹⁹ while the latest update provided follow-up of at least 7 years. The proportion of patients in whom treatment did not fail during the 7 years was significantly higher in the surgical arm than in the medical arm. A smaller difference in outcomes was noted after dose adjustments in the medical group. More patients in the surgical cohort, however, complained of side effects such as dysphagia, inability to belch or vomit, and hyperflatulence. Disease control was essentially stable between 5 and 7 years of follow-up. The authors concluded that surgery was more effective in controlling overall GERD symptoms, though postfundoplication side effects were a concern.

Another prospective trial from the United Kingdom compared laparoscopic Nissen fundoplication to PPI and reported follow-up at a median of 6.9 years.¹⁴² Some patients initially randomized to PPI therapy were offered the opportunity to undergo surgery. While both the medical and surgical cohorts reported an improvement in GERD-related symptoms after 12 months, further symptomatic improvement was noted in those patients subsequently undergoing surgery despite optimal PPI therapy.

A multicenter, European, prospective randomized trial comparing LARS to medical therapy with esomeprazole is ongoing (the LOTUS trial). Three-year outcomes in 288 patients assigned to LARS and 266 assigned to medical therapy were reported in 2008.²⁰⁴ The proportion of patients remaining in symptomatic remission was similar between the two groups (90% for LARS, 93% for medical therapy in an intention-to-treat analysis, $p = 0.25$). No major perioperative complications were noted and esomeprazole appeared to be well tolerated.

Recent reports have called attention to the observation that many patients are prescribed acid suppression medications after antireflux surgery. Spechler et al.^{205,206} reported on the long-term follow-up of patients with complicated GERD enrolled in the Department of Veterans Affairs randomized trial of medical versus surgical therapies. In the first report, almost half (46.9%) of the patients treated by fundoplication had taken acid suppression medications at some point during the 11- to 13-year follow-up period.²⁰⁵ In the second report, 62% of the surgically treated patients had used medications.²⁰⁶ The

reasons for and the necessity of acid suppression medication usage was not explored in this study. In contrast, Lord et al.²⁰⁷ reported on 86 patients who had symptoms after Nissen fundoplication severe enough to warrant evaluation with 24-hour ambulatory esophageal pH monitoring. Thirty-seven (43%) of these patients were taking acid suppression medications, and only nine of them (24%) were found to have abnormal pH scores. Heartburn and regurgitation were the only symptoms that were significantly associated with an abnormal pH study. Multivariable logistic regression analysis showed that patients with a disrupted or abnormally positioned fundoplication had a 52.6 times increased risk of abnormal esophageal acid exposure. Based on these data, most patients using acid suppression medications after antireflux surgery do not have abnormal esophageal acid exposure, and objective evidence of reflux should be obtained prior to restarting acid suppression medications in patients with symptoms after a fundoplication.

The goal of surgical treatment for GERD is to relieve and abolish reflux by reestablishing the GE barrier. This will alleviate symptoms related to reflux and protect the esophageal and laryngeal mucosa from reflux-related injury. The challenge is to accomplish this without inducing dysphagia or other untoward side effects. Dysphagia that existed prior to surgery usually improves following laparoscopic fundoplication. Temporary dysphagia is common after surgery and generally resolves within 3 months. Dysphagia persisting beyond 3 months has been reported in up to 10% of patients. In our experience, dysphagia, manifested by occasional difficulty in swallowing solids, was present in 7% of patients at 3 months, 5% at 6 months, 2% at 12 months, and a single patient at 24 months following surgery.³⁵ Others have observed a similar improvement in postoperative dysphagia with time. Induced dysphagia is usually mild, does not require dilatation, and is temporary, often related to edema from the surgery. Other side effects common to antireflux surgery include the inability to vomit and increased flatulence. Most patients cannot vomit through an intact wrap, though this is rarely clinically relevant. Hyperflatulence is a common and noticeable problem, likely related to increased air swallowing that is present in most patients with reflux disease and the inability to belch.

Objective Outcomes Following Antireflux Surgery. Laparoscopic fundoplication results in a significant increase in LES pressure and length, generally restoring these values to normal. The ability of an antireflux operation to restore esophageal acid exposure to normal depends on the type of fundoplication performed. Complete (Nissen) fundoplications generally are more reliable and durable than partial (e.g., Toupet) fundoplications at preventing pathologic acid reflux. Objective studies have shown that more than 90% of patients will have normal pH studies at 1 to 3 years following complete fundoplication, whereas only 50% of patients will have normal esophageal acid exposure following a partial fundic wrap.¹⁸⁷

Quality-of-life analyses have become an important part of surgical outcome assessment, with both generic and disease-specific questionnaires in use, in an attempt to quantitate quality of life before and after surgical intervention. In general, these measures relate the effect of disease management to the overall well-being of the patient.²⁰⁸ Most studies have utilized the Short Form 36 (SF-36) instrument, because it is rapidly administered and well validated. This questionnaire measures 12 different health-related quality-of-life parameters encompassing mental and physical well-being. Data from Los Angeles indicate significant improvements in scores for the area of bodily pain and in a portion of the general health index.³⁵ Most other measures were improved but failed to achieve statistical significance. Trus et al.²⁰⁹ have also analyzed SF-36 scores before and after LARS. In contrast to our data, scores in all fields were significantly better after surgery. In this study, preoperative scores were dramatically lower than were found in our study. Thus, the difference is likely to be secondary to the relatively high scores of our patients prior to surgery (perhaps reflecting good disease control on medical therapy) and to our small sample size.

Other investigators have also reported improvement in quality of life following antireflux surgery. Glise et al.²¹⁰ utilized two standardized and validated questionnaires, the Psychological General Well-Being Index and the Gastrointestinal Symptom Rating Scale, to evaluate quality of life in a cohort of 40 patients following LARS. Scores with both instruments were improved following antireflux surgery and better than in untreated patients. Of particular note was that scores were as good as or better than those of patients receiving optimal medical therapy. Velonovich et al.,²¹¹ using a 10-item health-related quality-of-life questionnaire specific for GERD, have also shown an improvement in quality of life following antireflux surgery.

Fernando et al.²¹² reported on quality of life after antireflux surgery compared with nonoperative management for severe GERD. Follow-up quality of life was measured using the SF-36, and heartburn severity was measured using the Health-Related Quality-of-Life (QOL) scale. Detailed outcomes were

available for 101 surgical patients and 37 medical patients. Mean QOL scores were better in the surgical group. More of the medical patients were dissatisfied with therapy. SF-36 scores were better in six of eight domains for surgical patients. These data support the notion that antireflux surgery, performed on properly selected patients, can significantly improve quality of life and may outperform medical therapy in this regard.

Anatomic Failure Following Antireflux Surgery. An important and often underemphasized point is that the rate of failure of fundoplication is largely dependent upon the size of the underlying hiatal hernia. Repair of large sliding and PEHs is associated with a higher risk of recurrent hiatal herniation compared to fundoplication for GERD in the setting of no or small hiatal hernias. Multiple potential explanations exist to explain this differential, including the presence of a widened hiatus with weakened or attenuated crural fibers that must be brought together under tension, the coexistence of esophageal body shortening, the generally older and frailer nature of patients with a PEH, and underlying anatomic, muscular, or connective tissue deficits that contributed to the pathogenesis of the hernia. In particular, the association between kyphosis and intrathoracic stomach is becoming increasingly recognized, as skeletal abnormalities likely are contributory to the pathogenesis of paraesophageal hiatal herniation.²¹³

The need for reoperation after fundoplication for GERD is only approximately 5% over the patient's lifetime, whereas the risk can run as high as 42% after repair of a giant PEH.²¹⁴ In a trial from Finland, objective outcomes were assessed by endoscopy and demonstrated a 40% disruption rate following open Nissen fundoplication and a 13% disruption rate following a laparoscopic procedure.²¹⁵ Despite these relatively high rates of objective breakdown, only 8% of patients in the open group and 2% in the laparoscopic group had undergone repeat operation for fundoplication failure.

A recent trial compared two techniques of laparoscopic PEH repair, with or without the use of a biologic prosthesis placed at the esophageal hiatus.²¹⁶ At 6 months, 9% of patients with the prosthesis and 24% of patients without mesh reinforcement had developed a recurrent hiatal hernia as assessed by a barium upper gastrointestinal examination, underscoring the potential for failure when operation is undertaken for PEHs. However, at a median of 58 months follow-up the authors updated their results and reported that greater than 50% of patients in both the mesh and nonmesh groups had objective evidence of hernia recurrence.²¹ This has led to controversy about the role of mesh at the hiatus, particularly in patients with large or paraesophageal-type hiatal hernias. It is likely that mesh use alone is inadequate to prevent hernia recurrence if tension on the crural closure or related to esophageal shortening is unaddressed. If mesh is to be used most experienced esophageal surgeons avoid the use of large or esophageal-encircling permanent mesh to minimize the risk of erosion. A small strip of synthetic mesh placed across the crural closure posterior to the esophagus may have less tendency to erode and lead to a reduction in hernia recurrence. Bridging the crura with synthetic mesh should be avoided since this leads to the highest risk for mesh erosion. An absorbable or biologic mesh bridge should also be avoided since this will lead to hernia recurrence in essentially all patients. Instead, a diaphragm relaxing incision should be used when the crura cannot be reapproximated or to do so requires excessive tension. Increasingly biologic or bioresorbable mesh reinforcement of the primary crural closure is being reported with good results.²² However, it is likely that mesh use increases the complexity of a reoperation if necessary, and has been shown to lead to a higher risk for the need for resection rather than redo fundoplication in the reoperative setting.²³

Relaxing incisions have been used for hernia repairs at other sites in the abdomen, and logically would be useful in patients with a widely splayed hiatus where the crura are unable to be approximated without tension. A right-sided diaphragmatic relaxing incision is easiest and usually suffices, but in a very large hiatus or in reoperations sometimes a left diaphragm relaxing incision is necessary. The defect created in the diaphragm should be repaired with permanent mesh to avoid herniation of abdomen contents into the thorax. The authors prefer a Gore Tex patch for this purpose and reinforce the primary crural closure with an absorbable or biologic mesh.²⁴

It is likely that efforts to reduce the high objective hernia recurrence rate after laparoscopic PEH repair will require addressing crural tension, esophageal tension from a shortened esophagus, and mesh reinforcement of the primary crural closure. When these adjunct techniques are added as necessary during a laparoscopic PEH repair the authors have reported a very reasonable short-term objective recurrence rate of 4%.²⁵

FUTURE DIRECTIONS

Medical therapy for GERD and antireflux surgery both have inherent drawbacks. Major limitations of acid suppressive medications include the inability to prevent regurgitation of weakly acidic or nonacidic refluxate and the need for chronic, continual therapy, not to mention the cost, inconvenience, potential side effects, and need for ongoing dietary and lifestyle modifications. In addition, current therapy does not address the main pathophysiologic contributor to the presence of GERD, the mechanically defective LES. Funduplications, while intended to permanently restore the LES, suffer from the potential for perioperative complications, a high initial cost, the risks inherent in general anesthesia, possible short- and long-term side effects, and inconsistent reflux control across centers. In addition, proper patient selection is critical and the operative technique is not well standardized, perhaps adversely affecting outcomes, particularly in inexperienced hands.

For all of these reasons, an interest remains to create means of restoring LES competence by medical or less invasive surgical or endoscopic techniques that are easily applied and highly reproducible. Medications such as baclofen, a γ -aminobutyric acid_B receptor agonist, have been utilized to decrease TLESRs, thereby decreasing GERD.²¹⁷ Similar investigational drugs are in the pipeline and likely will reach clinical practice soon. A number of endoluminal therapies have been devised and tested to date, the most promising of which are the transoral endoscopic fundoplication devices (EsophyX, EndoGastric Solutions, Inc., Redmond, Washington and Medigus SRS, Medigus, Ltd., Omer, Israel). A recent randomized control trial has shown that compared to PPI therapy a transoral fundoplication using the EsophyX device was associated with improved regurgitation symptoms.²⁶

Magnetic augmentation of the LES via a laparoscopically placed ring of small magnets (TORAX Medical, Inc., Shoreview, Minnesota) has proven efficacy for control of reflux in appropriate patients. The recently completed 5-year follow-up in 85 of an initial cohort of 100 patients showed no device erosions, migrations, or malfunctions. The GERD quality of life scores, frequency of PPI use and regurgitation symptoms were all improved compared to baseline. The ability to belch and vomit if necessary was preserved in all patients, and bothersome gas-bloat symptoms were reduced from baseline with a similar frequency of dysphagia symptoms.²⁷

Lastly, a novel device that provides intermittent electrical current to the LES via implanted wires and a pacer device (Endostim) has shown promising results in human trials from outside the United States.²⁸

Chapter 43

Esophageal Tumors and Injury

Jonathan D'Cunha and James D. Luketich

Key Points

- 1 The esophagus lacks a serosal layer. This is distinctive from other parts of the gastrointestinal tract. It is a major factor as tumor growth radially is not limited as in other gastrointestinal cancers.
 - 2 Esophageal perforation is a morbid clinical entity that has increasing incidence due to invasive procedures where iatrogenic injury accounts for over 50% of cases.
 - 3 The management of esophageal perforation is dictated by location of the perforation, the clinical condition of the patient, and the presence of underlying pathology.
 - 4 Esophageal stenting is a newer modality which has a role in esophageal perforation in well-selected clinical cases.
 - 5 The incidence of esophageal adenocarcinoma mirrors the rise in gastroesophageal reflux disease and obesity at an epidemic rate.
 - 6 In advanced stages, neoadjuvant therapy for esophageal adenocarcinoma suggests a survival advantage when chemoradiation is given prior to surgery for advanced disease. Early stage disease with minimal to no nodal involvement may go directly to surgery in selected cases.
 - 7 Surgery remains the primary therapy for esophageal cancer and options include transhiatal esophagectomy, Ivor Lewis esophagectomy, three-field esophagectomy, thoracoabdominal esophagectomy, and minimally invasive esophagectomy.
 - 8 Minimally invasive esophagectomy can be performed safely with excellent oncologic outcomes and lower morbidity than the open procedure.
 - 9 There are numerous palliative options for the patient with advanced esophageal cancer to maintain comfort, afford oral intake, and manage the symptoms of the disease in the end-stage situation.
-

INTRODUCTION

The esophagus is an active conduit that assists in transfer of food and secretions from the pharynx to the stomach. The esophagus is an organ of motility and provides no absorptive function. It also isolates the food and secretions from the mediastinum during transit.

Although the esophageal anatomy has been reviewed in the previous chapter, there are several points of consideration which need to be outlined as they are particularly relevant to surgical practice. First, three indentations can be identified on esophagram ([Fig. 43-1](#)). The cricopharyngeus muscle is the most proximal indentation and is a common location for iatrogenic perforation. The second indentation is the aortic arch which is just to the left of the esophagus and a common location for foreign body or food impaction. The third indentation is the left mainstem bronchus.

In the adult, the length of the esophagus is somewhat variable and certainly becomes relevant in the presence of a perforation, injury, or any requirement for reconstruction. The average overall length of the esophagus is 24 cm, with the esophagus beginning at the cricopharyngeus which is 14 to 16 cm from the incisors in an average-sized adult and ends at the gastroesophageal sphincter which is located 38 to 40 cm from the incisors when measured endoscopically.

The blood supply to the esophagus is segmental. The esophagus is vascularized by numerous arteries coursing through the lateral attachments and has an extensive submucosal collateral circulation. The cervical esophagus receives blood from the superior and inferior thyroid arteries. Multiple aortoesophageal arteries supply the intrathoracic esophagus and connect via collaterals with the inferior thyroid, intercostal, bronchial, inferior phrenic, and left gastric arteries. This blood supply is especially relevant during any operation on the esophagus and control of these segmental vessels is critical for a smooth operative and postoperative course.

1 The esophagus is composed of an outer longitudinal muscle layer and an inner layer of circular muscle. There is no serosal layer and this is a critical consideration when one thinks about disease processes of the esophagus. The lack of serosal layer is a distinguishing feature of the esophagus when compared with other parts of the gastrointestinal tract. The esophagus also has a unique submucosal layer which has a high fat content. This leads to an overlying mobility of the mucosa and propensity for proximal retraction such that care must be taken when placing sutures for reconstruction and minimizing the potential for anastomotic leak. The intramural lymphatic network is predominantly located within the submucosa of the organ. This is a rich lymphatic network which is especially relevant when one considers oncologic spread of tumor. There are also lymphatic channels within the lamina propria of the mucosa. All of this sets the stage for even superficial tumors to be associated with nodal metastases.

The esophagus is innervated by the autonomic nervous system. The cervical esophagus receives parasympathetic innervation through the recurrent laryngeal branches of the vagus nerve. Thus, injury to the recurrent laryngeal nerve not only produces vocal cord dysfunction, but also upper esophageal sphincter dysfunction.

ESOPHAGEAL INJURY

Perforation

Esophageal perforations are a major source of morbidity (10% to 60%) and mortality (4% to 50%); furthermore, following a perforation, 10% to 50% of patients develop strictures requiring dilations.¹⁻⁹ To date, no unified approach is available to treat these complex problems. Accurate diagnosis and early treatment are essential to the successful management of these complicated and often significantly ill patients. Some investigators suggest aggressive operative intervention (e.g., surgical exploration and repair or gastric conduit takedown with diversion) for patients with postesophagectomy intrathoracic anastomotic leak, while others recommend nonoperative management with stenting, jejunostomy feeds, perianastomotic drainage, and broad-spectrum antibiotics.^{5,10-15} Guidelines for either approach may work depending on the injury and thoracic surgeons must incorporate clinical judgment in the therapeutic decision-making process. The decision is influenced by the location and size of the perforation, the timing and mechanism, the degree of periesophageal soling and extravasation, coexisting pathology of the esophagus, the patient's overall clinical condition and perhaps most importantly, the experience of the surgeon.

Figure 43-1. Barium contrast esophagography showing the constriction caused by the cricopharyngeal muscle, aortic arch, and the left mainstem bronchus. Indentations of the esophagus made by external structures are important anatomic landmarks and are often the sites of perforation due to instrumentation.

2 The incidence of perforation has risen in the modern era due to the rise in endoscopic interventions. The causes of esophageal perforation are listed in [Table 43-1](#). Generally speaking the incidence of iatrogenic perforation (59%) far outweighs the incidence of spontaneous perforations (15%).¹² Other

less common injuries include foreign-body ingestion (12%) and trauma (9%). Ingestion of foreign bodies or caustic materials most commonly causes perforations in the anatomic areas just proximal or at narrowing (cricopharyngeus, level of aortic arch, and the level of left mainstem bronchus). Also included in the area at risk is the lower esophageal sphincter zone. External penetrating trauma can occur at any level but is seen more commonly in the cervical esophagus as the mediastinal portion is posterior and protected by the thorax. The morbidity and mortality of penetrating esophageal trauma is usually related to associated injuries including major vascular and airway structures.¹⁶ Blunt traumatic perforation of the esophagus is exceedingly rare.

The most commonly referenced and discussed perforation is the spontaneous one. This results from a sudden increase in intraesophageal pressure and associated with hyperemesis, childbirth, seizure, or prolonged coughing. Boerhaave syndrome is of special historical note, wherein patients develop perforation of the distal esophagus following extensive ingestion of food or alcohol. What follows is violent emesis resulting in a distal esophageal perforation, frequently into the left chest. The syndrome was named after Herman Boerhaave, who provided a detailed account of this condition in 1723 through a postmortem correlation of the perforation found in the High Admiral of the Dutch Navy, Baron Van Wassenaer.¹⁷ Legend has it that the admiral attempted to relieve his postprandial discomfort by self-induced vomiting after having feasted on roast duck and beer.

ETIOLOGY

Table 43-1 Causes of Esophageal Perforation

Instrumental
Endoscopy
Dilation
Intubation
Sclerotherapy
Laser therapy
Noninstrumental
Barogenic trauma
Postemetic (Boerhaave syndrome)
Blunt chest or abdominal trauma
Other (e.g., labor, convulsions, defecation)
Penetrating neck, chest, or abdominal trauma
Operative trauma
Esophageal reconstruction (anastomotic disruption)
Vagotomy, pulmonary resection, hiatal hernia repair, esophagomyotomy
Corrosive injuries (acid or alkali ingestion)
Erosion by adjacent infection
Swallowed foreign body

Clinical Features of Esophageal Perforation

The presenting features depend on the location of perforation and the time interval from perforation to presentation. Underlying comorbidities may also have an influence on the presentation and the patient’s physiologic reserve. Patients with cervical perforation present with dysphagia, neck pain, dysphonia, and subcutaneous neck emphysema. Intrathoracic perforations present with signs and symptoms of mediastinitis as follows: chest pain, tachycardia, tachypnea, fever, and leukocytosis. Perforations of the intra-abdominal esophagus may present as an acute abdomen with signs and symptoms as follows: pain, tachypnea, tachycardia, fever, and leukocytosis. More significant perforations and longer intervals to presentation contribute to the features of systemic sepsis, shock, and rapid deterioration.

Diagnosis

The diagnosis of esophageal perforation needs to begin with the clinician and their index of suspicion. Any patient who presents with pain following an endoscopic intervention needs to be carefully evaluated for perforation. The initial workup involves careful history and physical examination, laboratory studies including leukocyte count, and chemistry panel for acidosis. Chest x-ray is a good screening test for other diagnoses in the differential. Contrast esophagography remains the gold standard for diagnosis as the study will diagnose and localize the site of the perforation. This study also gives important information about coexisting pathology of the esophagus and the degree of

extravasation and its trajectory. Water-soluble contrast (e.g., Gastrografin) is the initial agent utilized, followed by thin barium to enhance the sensitivity of the study. Water-soluble agents demonstrate 50% of cervical perforations and 80% of intrathoracic perforations.¹⁸ Thin barium will identify 60% of cervical and 90% of intrathoracic perforations.¹⁹ If there is a chance of aspiration or high concern of tracheoesophageal fistula, thin barium should be used from the outset because the hyperosmolar water-soluble contrast agents may cause rapid pulmonary edema and respiratory compromise.

Computerized tomography (CT) scan is very useful in the diagnostic evaluation of the patient with concern for esophageal perforation. Often a CT scan is the first test obtained following a chest x-ray as it affords the clinician the ability to narrow the differential diagnosis. CT may be useful for identifying the site of perforation and any associated mediastinal or pleural fluid collections. It is very common for a CT scan finding to prompt thoracic surgical consultation or transfer and there is much additional information about the patient's overall status which is routinely utilized in the management plan. However, it should be emphasized that the barium swallow should be the procedure of choice unless there is a significant risk of aspiration.

Flexible esophagoscopy should be utilized liberally in the diagnostic evaluation of the esophagus and in the planning of treatment options, and in a significant number of cases it can also be used for intervention. The scope is utilized to directly visualize the area of perforation and identify any potential associated pathology. It has a sensitivity of over 95% and a specificity of 80% or even higher depending on the experience of the physician.²⁰ We routinely perform flexible endoscopy as the initial step in the operating room when considering all options for patient management. Concern has been expressed by some that the instrumentation of the esophagus and insufflation of air can worsen the extent of injury and pathology and we would agree with that in inexperienced hands. With care and experience, however, the flexible scope can be used safely and more effectively delineates the problem to aid in surgical decision-making that follows. The vast majority of patients will require an endoscopic evaluation at some point and the timing of this will depend on clinical presentation and findings on radiologic imaging. For very small leaks present in stable and nontoxic patients, when the contrast study shows little or no extravasation, we may opt to hold off on an endoscopy in select cases.

Management

3 The treatment of esophageal perforation is managed according to the clinical presentation which includes the location of the perforation, the degree of soilage, and the clinical condition of the patient. Generally speaking, the sooner diagnosis and a treatment plan is carried out, the better the outcome. The goal of treatment is to stabilize the patient, stop ongoing soilage, control the infection, and reestablish esophageal continuity. [Algorithm 43-1](#) provides general guidelines to the management of patients with esophageal perforations.

Nonoperative Treatment

For properly selected patients with esophageal perforation, nonoperative management may be appropriate. Generally, as thoracic surgeons, we err on the side of operative exploration intervention given the potential gravity of missing a clinically significant esophageal perforation with mediastinal soilage. Reports of nonoperative management date back to the 1960s in which successful management was accomplished in 18 highly selected patients with only one death.²¹ In the late 1970s, criteria were published for nonoperative management.²² Current guidelines for patients that can be managed nonoperatively include those with no transmural perforation or for whom transmural perforation represents a contained process. There must also be no associated esophageal pathology such as malignancy and no signs of systemic illness. The management of the nonoperative approach begins with the administration of broad-spectrum antibiotics (including antifungals), the suspension of oral intake, and vigilant clinical monitoring. The patient is followed clinically and reimaged as needed, generally within 48 to 72 hours with an esophagram and CT scan. If the patient improves during that time and testing is favorable, the diet may be advanced to clear liquids with the patient eventually being discharged on oral antibiotics and full liquids until reevaluation with imaging in clinic in 2 weeks. Any signs of sepsis such as fever, tachycardia, or leukocytosis suggest failure of this approach and further intervention should be expeditiously considered.

Algorithm 43-1

Algorithm 43-1. Evaluation and treatment of esophageal perforation.

Esophageal Stents

4 Endoscopic placement of endoluminal stents for perforations has been a concept which has been discussed for several decades.²³ In the last 10 years, the technology of stents has improved such that deployment is easier and our indications have expanded to include placement for perforations. Starting with small limited series,^{24–30} their use has expanded dramatically to the point that they have become one of the main tools in the management of select, contained perforations. Highly selected patients with perforations are candidates for stenting in the context of a thoracic surgical practice according to the principles outlined in this section. Our own investigations and use in our practice has found that esophageal stent placement for perforations facilitates source control, may minimize stricture formation, and frequently allows for early oral intake. However, success depends on a uniform approach that focuses on appropriate patient selection, proper stent placement technique, thorough drainage procedures which cannot be underemphasized, and meticulous postoperative care. Our recommended uniform approach is presented here and this approach has yielded excellent results.^{31–33}

DIAGNOSTIC EVALUATION

A computerized tomography (CT) scan, with or without oral and intravenous (IV) contrast, is a good initial diagnostic test. The role of a CT scan is to help determine whether additional source-control measures are needed (e.g., tube thoracostomy, decortication). We frequently perform the contrast esophagram second as the barium may interfere with the CT scan and the only reason we omit this step is in the case of aspiration risk. The barium esophagram is regarded as a real-time image, whereas the contrast delivery of the CT scan does not provide the same functional and anatomic details of the site and tracking of the leak, thus we prefer both when possible.

PATIENT SELECTION

For perforations proximal to the cricopharyngeus, stents have little or no role. For perforations 2 cm or more distal to the cricopharyngeus, a stent may work if the proximal extent seats just below the cricopharyngeus muscle. If the stent seats at or above the cricopharyngeus, patients experience intolerable foreign-body sensations during deglutition and reflux and coughing are generally severe. Also of note, stents placed in the proximal esophagus may cause pressure and compression of the posterior membranous trachea leading to dyspnea and, in severe cases, critical airway compromise. If a stent is considered in the proximal esophagus, the physician should strongly consider performing a simultaneous bronchoscopy to assess airway patency. Perforations below this area may be good

candidates for stenting when there is limited perforation, and there is good purchase of esophagus above and below the site of the perforation. This might include perforations associated with malignancy and in benign diseases such as iatrogenic perforation, Boerhaave syndrome, and select cases of achalasia. Patients with perforations from near-obstructing cancers can be ideal candidates for stents as the stent will purchase well against the tumor, leading to sealing of the perforation and relieving any coexisting blockage above or below the perforations. In addition, operating on perforated cancers can be a significant clinical problem as this may occur at the initial diagnosis or the endoscopic ultrasound (EUS), or may occur during chemo and radiation, thus making stenting our procedure of choice in the setting of cancer.

Initial broad-spectrum antimicrobial therapy is directed to cover common gram-negative bacteria, anaerobic bacteria, and fungi. We generally use a beta-lactam agent in combination with fluconazole, which is usually sufficient. We adjust therapy to culture findings. Duration of therapy is patient dependent, but it is typically continued for 10 to 14 days after resolution.

In addition to antimicrobial therapy, we tailor further source control in accordance with clinical, CT scan, endoscopic, and intraoperative findings. We emphasize aggressive source control, and operative drainage of any extraluminal material. Stent placement without drainage in the setting of mediastinal soilage is a risky approach and if it is done, one may question whether the perforation was small enough to need intervention and, if larger, we would typically perform a VATS or thoracotomy to debride any soilage. If patients deteriorate clinically following any treatment, consideration of the presence of undrained sepsis should always be considered. At times, a patient might require several interventions to control the local and regional sepsis.

Source control measures vary depending on clinical and anatomical findings:

Mediastinal air (no fluid): antibiotics only without additional source control measures.

- Mediastinal fluid collection or abscess: operative drainage; the approach varies by anatomical location:
 - Neck and superior mediastinum: lower neck incision with blunt mediastinal dissection, irrigation, open packing, and, if deemed appropriate, drain placement.
 - Posterior mediastinum at any level: right thoracoscopy or thoracotomy with wide pleural incision, drainage, irrigation, and large-bore chest tube(s) placement.
 - Lower posterior mediastinum only: left thoracoscopic or open drainage.
- Free-flowing pleural effusion: large-bore tube thoracostomy.
- Empyema: thoracoscopic or open decortication.

STENT SELECTION

Numerous stents are available for use. We prefer the Wallflex fully covered stent and find that the longer stents (15 cm) work better to cover defects and minimize migration.

STENT PLACEMENT TECHNIQUE

We perform our procedures in the operating room and with the patients under general endotracheal anesthesia. The key components of our stent placement technique are the following:

1. Position: supine position with the head of the bed elevated 30 degrees.
2. Intraoperative fluoroscopy:
 - Radiopaque skin markers: large-bore IV needles taped to the skin. Lock the fluoroscopy arm into position once the desired image has been obtained and before skin marker placement; moving the fluoroscopy arm after marker placement may lead to inaccurate marking.
 - At times, we will use intraoperative esophagram: if the leak is small, we will inject contrast through the esophagoscope to clearly identify it; we always confirm leak sealing with contrast injection after stent placement. We use isomolar and water-soluble contrast dye (iodixanol [Visipaque]; GE Healthcare Inc, Princeton, NJ) to minimize respiratory complications in case of aspiration.
3. Wire of choice: superstiff, angled or straight tip, 0.035-in (0.8-mm) diameter, 260-cm length.
4. Stent position:
 - Minimum coverage: at least 3 to 4 cm above and below the leak or perforation.
 - Minimum distance from cricopharyngeus muscle (upper esophageal sphincter): 1 to 2 cm.
 - Distal end position: we avoid the distal end from crossing the GE junction.

5. Stent foreshortening or “jumping” on deployment: this varies by stent.
6. Intraoperative evaluation of stent position and proper sealing: every stent is placed and evaluated with fluoroscopic guidance and endoscopy.
7. Tools and techniques for stent repositioning (if stent is too distal or too proximal): the “rattooth” forceps is the best tool to pull the stent proximally if needed after deployment. If we need to advance the stent in a patient with a gastric conduit, then we will advance the gastroscope into the distal stomach, retroflex, lock the “rat-tooth” grasper on the distal end of the stent, and push the gastroscope forward.
8. Indications for immediate stent removal: we never leave a stent in place if it is not in perfect position, angulated too much, or obstructed.

POSTSTENT MANAGEMENT

1. Nutrition: enteral feeding access should be ensured as soon as possible, preferably at the time of endoscopic and operative interventions. We place an operative jejunostomy tube or percutaneous endoscopic jejunostomy tube in the occasional postesophagectomy patient who does not already have enteral feeding access. In patients with perforations, we place a percutaneous endoscopic gastrostomy (PEG) tube at the time of endoscopic or operative intervention but before stent placement. In our experience, placing a PEG tube has no effect on the perforation; placing a PEG tube after stent placement will likely displace the stent.
2. Aspiration and reflux precautions: these precautions are imperative in all postesophagectomy patients and in patients with stents that cross the gastroesophageal junction.
3. Postprocedure follow-up:
 - a. Chest radiograph: we obtain chest radiography immediately after the procedure and daily thereafter to monitor for migration.
 - b. Sepsis resolved: we wait until the patient is able to swallow appropriately; then we perform an esophagram.
 - c. Ongoing sepsis: we thoroughly reassess the patient; ongoing sepsis is generally due to poor source control and/or nonsealing of the leak or perforation. Reintervention is then tailored to the situation but might require aggressive surgical intervention and stent removal and/or replacement.
 - d. Stent migration: mandates replacement unless leak has resolved. This is typically not an emergency but should be addressed in a timely fashion.
4. Resumption of oral intake: this depends on the clinical scenario. A speech pathologist evaluates every patient before an esophagram. Only patients who are safe to swallow undergo an esophagram. Oral intake is then resumed.
5. Eventual stent removal or exchange: We generally repeat endoscopy at 3-week intervals and remove the stent. If a small leak persists, we restent so that the distal end of the stent is slightly proximal or distal to that of the previous stent to allow the area of inflamed gastric mucosa to heal.
6. Pain: pain appears to be less common in patients with leaks and perforations than in patients with malignant strictures. Persistent pain should prompt reevaluation, because it might represent ongoing mediastinal or pleural contamination.

Operative Treatment

The operative management of esophageal perforation is dictated by the location of the injury, extent of injury, and underlying pathology. The operative approaches include the following options: drainage alone, primary reinforced repair, esophagectomy with immediate/delayed reconstruction, and esophageal exclusion.

Perforations of the upper third of the esophagus to the level of the carina and treated by cervical drainage that is approached via a left neck incision as depicted in [Figure 43-2](#). Traditionally it is not necessary to find or close the perforation as this will seal during the process of healing. In order for this to be successful, however, wide and complete drainage must be accomplished. The posterior prevertebral fascia is opened completely to accomplish this. Preoperative imaging via CT scan will aid in ensuring that the important areas of contamination are addressed surgically. In the operating room we liberally use on-table flexible endoscopy to evaluate the defect and the location of the hole. If the hole is identified and it is small, we advocate for closure of the hole. The neck incision is loosely closed with staples over a drain. Postoperatively, broad-spectrum antibiotics are continued. One may consider

a gastrostomy or jejunostomy tube for nutritional access during the time the patient is NPO. Typically at 5 to 7 days postoperatively a contrast esophagram is obtained, the patient's diet is advanced, and the drain is removed. If there is continued leak, the patient is left NPO or on clear liquids and restudied in 1 week. There should be no distal obstruction on the contrast study and if there is a stricture that prevents normal contrast flow, we advocate for dilation to aid in eventual closure of the esophageal fistula. As long as there is no underlying pathology and there is distal flow through the esophagus in the presence of adequate drainage, the esophageal perforations will heal spontaneously.

Perforations of the middle third of the esophagus are best approached through the middle third of the esophagus via a right 5th interspace posterolateral thoracotomy. After adequate IV access and arterial line placement, a single-lumen tube is placed and bronchoscopy/esophagoscopy is performed. The single-lumen endotracheal tube is changed to a double-lumen endotracheal tube and the patient is positioned in the left lateral decubitus position. We routinely start thoracoscopically, but typically these patients are very ill and thoracotomy is indicated early. At the time of entry into the chest, an intercostal m. flap is routinely taken. We use papaverine solution to enhance blood flow and great care is taken not to injure the flap when the retractors are placed. A Doppler is routinely used to confirm blood flow in the flap. All pleural collections are drained, the lung is decorticated, and the site of perforation identified after opening the posterior mediastinal pleura. Necrotic tissue at the site of the perforation is debrided and the esophagus is mobilized. A vertical myotomy is performed to expose the mucosa and the full extent of the tear ([Fig. 43-3](#)). The mucosa is repaired with interrupted or running absorbable suture. The muscular layer is reapproximated with interrupted fine silk suture. On-table endoscopy is performed to ensure the leak is repaired. The intercostal m. is then secured as an onlay patch. Large chest tubes are placed and a 10-French Jackson–Pratt drain is left in the area of the repair and placed to bulb suction. Typically nutritional access is not addressed at the time of the index operation as the patients are quite ill, and this can be accomplished at a later date. On POD 7, a contrast study is obtained and if there is no leak, the diet is advanced. Persistent leaks are treated with JP drainage, provided CT imaging demonstrates that there are no undrained collections. Esophageal dilation may be required to ensure proper forward flow. Reoperations for adequate drainage may be required. Esophageal stenting may be used to exclude the leak provided that there is adequate drainage and the principals described in the stenting portion of this chapter are followed. If the repair breaks down or there are signs of clinical sepsis, esophageal exclusion may be required with cervical esophagostomy, esophageal resection, and gastrostomy tube. When the patient recovers and walks into clinic begging for reconstruction (this usually occurs at 6 to 12 months postexclusion), they may be considered for reconstruction most commonly approached as a substernal gastric pull-up.

Figure 43-2. Approach for drainage of a cervical esophageal perforation. **A:** Skin incision parallel to the anterior border of the left sternocleidomastoid muscle, extending from the level of the cricoid cartilage to the sternal notch. **B:** With the sternocleidomastoid muscle and carotid sheath retracted laterally and the trachea and thyroid gland medially, blunt dissection along the prevertebral fascia in the superior mediastinum is carried out. Injury to the recurrent laryngeal nerve in the tracheoesophageal groove must be avoided. **C:** Schematic drawing of the prevertebral space drained by this cervical approach. **D:** Two 1-in rubber drains placed into the superior mediastinum are brought out through the neck wound to allow establishment of an esophagocutaneous fistula, which usually heals spontaneously.

Figure 43-3. Primary repair of esophageal perforation. The edematous mucosa pouting through the muscular defect (*inset*) is grasped with Allis clamps and elevated. A 1-cm vertical esophagomyotomy is made at either end of the muscular defect to expose the entire limits of the tear. This is facilitated by using a right-angle clamp to direct muscularis away from underlying submucosa around the entire circumference of the tear. The result of this mobilization is exposure of a circumferential rim of normal submucosa that can then be closed.

Perforations of the distal third of the esophagus are approached via a left 7th intercostal space thoracotomy. Similar to the approach for middle-third perforations, after adequate IV access and arterial line placement, a single-lumen tube is placed and bronchoscopy/esophagoscopy is performed. The single-lumen endotracheal tube is changed to a double-lumen endotracheal tube and the patient is positioned in the left lateral decubitus position. Thoracoscopy may be an option, but typically these

patients are very ill and thoracotomy is indicated. At the time of entry into the chest, an intercostal m. flap is routinely taken and care is taken not to injure it as retractors are placed. The chest is drained, lung decorticated, the perforation identified, and the repair performed as described above.

The operative treatment in the presence of underlying pathology deserves special attention and can be quite challenging. If there is distal obstruction, this must be dealt with. Strictures can be dilated or stented and often support the healing of a proximal perforation. Patients with achalasia who are perforated during pneumatic dilation are especially challenging. Many are candidates for nonoperative intervention as they have small perforations that are asymptomatic and the patients are clinically nontoxic. This is acceptable provided the distal obstruction has been relieved. For those who fail nonoperative management or are not candidates, operative management should be tailored to the individual and their pathology. In patients with preserved motility, the perforation should be repaired primarily and a vertical myotomy should be performed 180 degrees opposite the injury. These patients should have a nonobstructive fundoplication performed. For stable patients with advanced achalasia, esophagectomy should be considered. For unstable patients, esophageal exclusion should be performed.

Unstable patients with advanced pathology such as cancer should undergo esophageal exclusion. This includes stapled esophageal diversion with resection of the diseased segment of the esophagus. A linear stapler is deployed on the esophagus proximally and at the gastroesophageal junction. The esophagus is resected. An end cervical esophagostomy is created saving as much esophageal length as possible. Pleural drainage is accomplished. Subsequently the patient undergoes placement of gastrostomy (+/- jejunostomy tube) with repair of the diaphragmatic defect from the abdominal side via laparoscopy or laparotomy. The components of operation may be staged based on the severity of patient illness. If the patient survives and is a candidate for reestablishment of continuity, this can be investigated at a later date when they recover. In the current healthcare climate, the presentation of an advanced perforated malignancy, stenting and drainage may have a role. Additionally, consideration should be given to end-of-life discussions depending on the extent of the cancer.

Caustic Injury

Caustic burns of the esophagus result from ingestion of caustic substances. In children, ingestion is typically accidental, but in adults, ingestion is often intentional as part of a suicide attempt. Although prevention programs, consumer product safety commissions, lobbying by the medical profession, and heightened consumer awareness have significantly diminished the devastating effects of caustic ingestions, caustic injury of the esophagus remains a significant medical and social problem. The two most common ingestion scenarios are accidental ingestions in children younger than 5 years old and suicide attempts in individuals 15 to 40 years old. The most commonly ingested agent is an alkaline household liquid cleaner. Although mortality from caustic ingestion is low, the morbidity associated with caustic ingestions is significant. Acute morbidities include perforation and necrosis, and late morbidities, which are more prevalent, include stricture formation and cancer.

The extent of injury to the esophagus caused by ingested caustic material is dependent on the volume and nature of the ingestion. Injuries resulting from ingestion of liquids are much more severe than those caused by ingestion of solids. The patient usually spits particulate matter out and, thus, it rarely moves beyond the oropharynx. Liquid caustic agents contribute to pathology down the length of the esophagus. Strong acid and alkali ingestions comprise the majority of caustic ingestions. These substances are sold in various liquid and solid/particulate forms. The most commonly ingested strong acids include industrial and swimming pool cleaning solutions, battery fluids, and antirust compounds. Commonly ingested strong alkaline-containing substances include household cleaning products and personal hygiene products. The most commonly ingested weak alkali is ammonia hydroxide, which is found in most bleach solutions. Weak alkalis cause much less injury and require far less therapy.

The burns from acid ingestion cause coagulative necrosis and a superficial eschar that protects the deeper layers of the esophagus from damage. Fortunately, acids tend to taste bitter and cause immediate pain, thus the patient will usually spit the substance out well before it reaches the esophagus and stomach. When acids are ingested in liquid form, they move quickly, typically spare the oropharynx, and produce skip injuries to the esophagus. Acids in liquid form cause gastric and duodenal injury more frequently than esophageal injury.

Alkaline burns are characterized by liquefactive necrosis, leading to far greater penetration at the level of the oropharynx and esophagus. Solid alkali has a propensity to adhere to the oropharynx, whereas liquid alkali is rapidly swallowed. Thus, liquid alkali results in more distal esophageal and gastric injury. Frequently there is penetration of all layers of the esophagus causing substantial

secondary edema. Commensurate with this, the potential for perforation and circumferential scar formation is greatest with an alkaline ingestion. In contrast to acid ingestion, alkali substances are typically odorless and tasteless, which enhances the potential for deeper injury.

Management

The initial clinical presentation comprises oropharyngeal pain; irritability; and, in severe cases, excessive salivation, dysphagia, and airway compromise. Ingestion of particulate caustic substances results in signs of contact readily visible in the oropharynx. Hoarseness and stridor are signs of serious airway injury that mandate intubation. Retrosternal pain, neck crepitus, and sudden onset of epigastric pain imply full-thickness esophageal damage. Many patients present without symptoms and a significant proportion have injuries that will require intervention. Thus, a 24-hour period of observation is reasonable, even for asymptomatic patients, especially if there is any question about the circumstances of the ingestion or extent of injury.

As with any acute situation, management should begin with the standard assessment of the ABCs (airway, breathing, and circulation) ([Algorithm 43-2](#)). Most caustic ingestions involve the oropharynx, lips, and gums. As with most foreign-body ingestions, the most common sites for pathology within the esophagus are its three areas of narrowing: the cricopharyngeus, the level of the aortic arch, and the gastroesophageal junction. A stable patient may undergo imaging via posteroanterior and lateral upright chest and abdominal radiographs to evaluate for pleural effusion or free air. CT of the chest and abdomen can provide important anatomical definition of injury. Patients with no visible symptoms or only lip swelling or redness can be observed in the hospital or a short-stay unit for 24 hours to ensure they can tolerate oral feedings. This is typically for pediatric patients. Patients with oral lesions should undergo esophagoscopy and bronchoscopy. The bedside insertion of a nasogastric or orogastric tube is discouraged when the extent and depth of injury have not been fully evaluated.

After radiographic imaging, rigid or flexible esophagoscopy to characterize the location and extent of injury should be the next course of investigation. This instrumentation should be performed within the first 24 hours as the risk of procedural complication increases with time. The indications for esophagoscopy include stridor, vomiting, drooling, and intentional ingestion. Caution should be used when moving beyond the first sign of pathology below the cricopharyngeus. If there are respiratory symptoms, laryngoscopy and bronchoscopy should be performed. When injury is identified, the standard grading of the esophageal burn should be reported ([Table 43-2](#)).

Patients with grade I injuries have superficial burns causing edema and hyperemia. These patients can be observed, a normal diet can be advanced, and the patient ultimately can be followed in an outpatient clinic. Superficial grade I injuries cause mucosal sloughing and should heal without a stricture. Grade II injuries penetrate into the muscular layer of the esophagus and can result in either patchy (IIA) or circumferential (IIB) injury. Ulcerations (superficial and deep) and pseudomembranes are found during endoscopy. Once circumferential injury is identified, the risk of stricture formation increases dramatically. Grade III injuries are full-thickness injuries, and mediastinitis or peritonitis occurs within 48 hours. Grade III findings are characterized by gray mucosal slough, thrombosed submucosal vessels, and black eschar. All grade III burns and >75% of circumferential grade IIB burns cause esophageal stricture and, as expected, are associated with a higher incidence of infection.

Algorithm 43-2. Proposed algorithm for evaluation and management of acute caustic ingestion.

Acute management of caustic ingestion should be dictated by the endoscopic grading of the esophagus and the clinical status of the patient (Algorithm 43-2). Patients should be evaluated for using endoscopy to grade the injury. If there is no evidence of perforation, patients with mild exposure (e.g., bleach or detergent ingestion) can be observed for 24 to 72 hours (depending on the clinical presentation). Generally, patients should be kept *nil per os* (NPO) until pain free. Enteral feedings can likely be introduced within 48 hours for all patients with grade I or IIA burns.

CLASSIFICATION

Table 43-2 Endoscopic Grading of Acute Caustic Injury to the Esophagus

Injury	Endoscopic	Depth of Grade Appearance Injury
I	Superficial hyperemia	Mucosal
IIA	Sloughing mucosa, superficial ulceration	Patch partial thickness
IIB	Deep ulceration	Circumferential
III	Eschar, necrosis	Full thickness

Patients with grade IIB or grade III esophageal burns without evidence of perforation should be placed in a monitored setting, kept NPO, and given IV fluids and IV antibiotics (penicillin derivative or clindamycin). Patients should also be maintained on proton pump inhibitors to reduce acid exposure of the esophagus as this may decrease the stricture incidence. Steroid administration is controversial, does not prevent stricture formation, and may mask findings in the serial abdominal examination. If corticosteroids (2 to 2.5 mg/kg/d) are used, they should be instituted within the first 24 hours of ingestion and for 3 weeks thereafter. Early introduction of parenteral nutrition is essential for all patients with esophageal perforation and for patients with poor gastric motility. Open gastrostomy is helpful for patients with grade IIB or III burns. Depending on the extent of injury, the patient may require mechanical ventilation. Esophagram (or CT scan with oral contrast) may be used as an adjunct evaluation. If free contrast extravasation into the mediastinum is visualized, drainage of the

mediastinum into the pleural space is indicated. Further, esophageal resection may be required with findings of necrosis. On occasion, a contained mediastinal leak, which returns contrast material back into the esophagus, may be observed without the need for immediate drainage. Pneumoperitoneum is an absolute indication for laparotomy and resection of all dead tissues. Laparoscopic evaluation may be useful to evaluate the abdomen if there is isolated mediastinal pathology.

Strictures of varying degrees occur in almost all patients and, thus, careful follow-up is recommended after a caustic ingestion. The esophagus and stomach should be evaluated via barium swallow 3 weeks, 3 months, and 6 months after the ingestion to rule out stricture formation or gastric outlet obstruction. Esophagogastroduodenoscopy (EGD) is typically performed 3 weeks after the ingestion for full evaluation. Early endoscopy is warranted during the phase of cicatrix formation, and dilation is repeated at varying intervals. The interval for intervention is patient dependent and clinically dictated by the amount of dysphagia or interval to recurrence of dysphagia, the initial severity of burn, and findings on radiographic studies.

Operative Considerations

Delay in the diagnosis of esophageal perforation from caustic ingestion is uniformly fatal. Isolated mediastinal air can be managed with direct inspection of the thorax, open débridement of necrotic tissue, and drainage of the mediastinum. Caustic esophageal perforations are best managed with urgent esophagectomy. Removal of the entire esophagus is possible through a transhiatal approach followed by a cervical esophagostomy, gastrostomy, and feeding jejunostomy. Patients with extensive full-thickness esophageal and gastric necrosis should undergo total esophagogastrectomy with cervical esophagotomy and feeding jejunostomy. Of course, any operative intervention should include assessment of other organs involved and complete drainage/resection of necrotic tissue.

In most patients, management of esophageal strictures that develop as a result of caustic burns is the primary operative consideration. Circumferential grade IIB burns can be managed with an open gastrostomy and insertion of a string through the gastrostomy that exits transnasally. Four weeks after the burn, serial dilations using progressive antegrade bougienage from the oropharynx or retrograde stringing bougienage through the gastrostomy is effective. Retrograde string bougienage or antegrade dilations should be performed at 2- to 3-week intervals for consecutive dilations. Optimal caliber bougienage is 48 to 50 for adults and 34 to 36 for children. Esophageal stenting is a newer approach for second-degree esophageal burns, which may be more palatable than string bougienage. A removable, fully covered stent is placed endoscopically and left in place for 3 weeks. It can then be removed. Recent reports have suggested that this is an appropriate intervention to prevent stricture formation in some patients. Injection of the stricture with triamcinolone (30 mg/mL) also may be effective, especially in those strictures that are focal.

Esophageal replacement is usually considered if a stricture fails to resolve after 1 year of dilations, stricture injections, and antacid therapy. Malignant degeneration is possible at the area of the stricture, and esophageal cancer occurs at a 1,000-fold greater frequency in individuals with a caustic injury to the esophagus than in the general population. Any change in symptoms warrants radiographic and endoscopic evaluation. Options for esophageal replacement include reverse gastric tube, gastric pull-up, and colon or jejunal interposition. Most centers today use the gastric pull-up or colon interposition (retrosternal). Short-term complications of replacement are those typical of esophagectomy; anastomotic leak and poor conduit vascularity are the most feared complications. Long-term complications depend on the type of replacement. Stomach conduits have the problem of continued gastric acid secretion and the possibility of reflux and dysplasia. The colon (and the jejunum) can become redundant and require revision. Overall, there is no optimal substitute for one's own esophagus and efforts should be made to preserve it at all costs.

Foreign Body

Foreign-body ingestion and food bolus impaction are common occurrences that physicians can encounter when dealing with the esophagus. A majority of foreign bodies have been known to pass through the gastrointestinal tract spontaneously. However, roughly 10% to 20% of cases may require nonoperative intervention, with <1% requiring surgery.³⁴⁻³⁶ A large percentage of objects that do not pass spontaneously remain in the cervical esophagus.

Foreign-body ingestion is most commonly seen in children between the ages of 6 months and 3 years, with over 100,000 new cases occurring in the United States annually.³⁷ Pediatric foreign-body ingestion is typically accidental and most frequently involve coins, followed by toy parts, batteries, bones, and

food.³⁷ Cases of foreign-body ingestion in adults are seen more commonly among the psychiatric patients, patients with impaired cognition such as the elderly, and incarcerated individuals seeking secondary gain.³⁴⁻³⁶

Endoscopy is the choice of management when nonoperative intervention is a viable option. Timing of endoscopy is indicated by the risk of esophageal wall damage or aspiration, as well as the clinical status of the patient. Urgent intervention using endoscopy may be required in patients with severe distress, unable to swallow their own secretions, or with foreign bodies that are batteries or have sharp edges. Patients who do not fit these criteria and have no evidence of severe obstruction can be handled less urgently as most foreign objects will pass spontaneously.

Retrieval is the goal when dealing with foreign bodies that are not subjected to spontaneous passing. General anesthesia is recommended during the entirety of this procedure. Flexible endoscopy is the preferred method for most foreign bodies. A rigid endoscope is useful in the retrieval of foreign bodies lodged in the proximal esophagus at the level of the cricopharyngeus muscle. Rigid esophagoscopy is a rarer procedure and one should be familiar with the technique. Often senior surgical help should be sought to accomplish the procedure safely and effectively because this technique is rarely used in current training. Using either approach, the object should be reoriented with a grasper and removed safely. When using the flexible esophagoscope, we have found the overtube to be a very useful tool for removal of foreign bodies such that the esophagus is not injured proximally upon extrication of the object. Esophagotomy may be required when the lodged foreign bodies are large, have sharp edges, are embedded in the mucosa, or exceed the diameter of the rigid endoscope in all orientations. Following removal of the foreign body, completion esophagoscopy and contrast esophagoscopy should be performed to rule out injury. If there is a perforation, it should be managed according to the algorithm in [Algorithm 43-1](#).

BENIGN NEOPLASMS

[Table 43-3](#) represents a list of all benign neoplasms of the esophagus. All of these lesions are rare, with leiomyoma making up roughly 60% to 70% of all cases.^{38,39} Esophageal polyps are also seen frequently in large referral centers and will be discussed. Other listed benign neoplasms of the esophagus will not be discussed in this chapter, but the possibility of an occurrence should be noted, especially during the formulation of a differential diagnosis.

Leiomyoma

As mentioned above, leiomyomas are by far the most common benign neoplasms of the esophagus, accounting for roughly 60% to 70% of these cases.^{38,39} The incidence of leiomyoma of the esophagus reported in autopsy range from 0.005% to 5.1%.⁴⁰ Histologically, approximately 80% of leiomyoma originates from the muscularis propria and are located intramurally. Upon visual inspection of the esophagus, they are typically located in the middle and lower esophagus. They have been reported to present as single lesions. Because leiomyomas are slow-growing tumors, the size of these lesions often do not change for many years. Over 50% of these patients often are asymptomatic due to the nature of the growth.³⁹

From Nemir P Jr, Wallace HW, Fallahnejad M. Diagnosis and surgical management of benign disease of the esophagus. *Curr Probl Surg* 1976;13(3):1-74, with permission.

[Algorithm 43-3](#) depicts the process for evaluating and treating esophageal leiomyomas. Evaluation of a patient suspected of having a leiomyoma should begin with a barium swallow, endoscopy, EUS, and CT scan of the chest. [Figure 43-4](#) depicts the typical appearance of an esophageal leiomyoma located in the midthoracic of the esophagus. This smooth walled characteristic may indicate that mucosa is not involved and that the lesion is contained in the submucosal layer. [Figure 43-5](#) offers the endoscopic appearance of a distal esophageal leiomyoma. The utility of the EUS also gives clinicians the ability to ascertain the layer of origin of the mass. EUS in combination with fine-needle aspiration (FNA) may be used to obtain tissue for histologic studies such as immunohistochemical (IHC) analysis. IHC analysis is helpful in differentiating leiomyomas from other more aggressive pathology such as leiomyosarcomas and gastrointestinal stromal tumors (GISTs) and should be incorporated into the surgical planning for diagnosis.⁴¹ However, FNA should not be routinely performed due to the association between preoperative biopsy and mucosal perforation at the time of surgical enucleation.⁴²

Treatment in asymptomatic patients with tumors <3 cm is currently controversial. Nonoperative surveillance or resection should be discussed with patients in this cohort. The surgical removal of an esophageal leiomyoma is indicated with the development of symptoms of dysphagia, an increase in tumor size, mucosal ulcerations, and to definitively rule out a malignant process such as a leiomyosarcoma.

Figure 43-4. Esophagram of a leiomyoma. The acute angle at its junction with the esophageal wall is typical. (Reproduced with permission from Orringer MB. Tumors of the esophagus. In: Sabiston DC Jr, ed. *Textbook of Surgery*. 13th ed. Philadelphia, PA: WB Saunders; 1986:736.)

Algorithm 43-3

Algorithm 43-3. Evaluation and treatment of esophageal leiomyoma.

Like other lesions of the esophagus, the surgical approach is dependent on tumor location, size, and characteristics. The typical approach to leiomyomas originating from the mid to distal esophagus is via the right thorax. Surgical extramucosal enucleation is an approach that has shown excellent results with patients with leiomyomas that are less than 8 cm without annular characteristics. Mortality was found to be less than 1% for this approach with over 90% of patients symptom free at 5 years.⁴³

Minimally, invasive approaches to enucleation have also been shown to be effective, particularly in tumors smaller than 5 cm. Zaninotto and colleagues performed 11 video-assisted enucleations of leiomyomas of the esophagus with no major morbidities, including death or postoperative leaks.⁴⁴ Leiomyomas greater than 8 cm or annular in character usually require esophageal resection. Approaches and techniques to esophageal resection will be covered later in this chapter.

Fibrolipomas and Fibrovascular Polyps

Fibrolipomas and fibrovascular polyps are rare tumors of the esophagus that often present as an intraluminal mass originating from the cervical portion of the esophagus. Clinically, these tumors will decrease intraluminal diameter and volume, and patients will present with dysphagia. The growth of these tumors are influenced by the peristaltic action of the esophagus, causing these lesions to elongate over time.⁴⁵ The stalk-like nature of esophageal fibrolipomas can be seen endoscopically and subsequently should be removed. Cervical esophagotomy or right thoracotomy approaches may be required for resection if the size of the lesions restrict mobility. In rare instances, patients can present with their polyp protruding from their mouth after an episode of coughing or emesis (Fig. 43-6). Polyps may also flip and cause blockage of the airways and should be excised to avoid this occurrence.

MALIGNANT NEOPLASMS

Tumors of the esophagus include adenocarcinoma, squamous cell carcinoma, small cell carcinoma, leiomyosarcoma, rhabdomyosarcoma, fibrosarcoma, liposarcoma, lymphomas, and metastatic lesions from the other sites. Adenocarcinoma and squamous cell carcinoma are the most common, with adenocarcinoma emerging in recent years in epidemic type rates of increase (Fig. 43-7). Recent analysis of incidence has demonstrated that there are about 17,000 cases diagnosed each year in the United States. About 14,000 will die annually. The lifetime risk of developing esophageal cancer is 0.5%, with a slightly higher incidence in males. Risk factors include tobacco, alcohol, and obesity. Tylosis is the only recognized family syndrome that predisposes patients to the development of esophageal cancer. It is an autosomal dominant disorder that has been mapped to chromosome 17q25.⁴⁰ These patients have a 95% risk of developing squamous cell carcinoma of the esophagus by age 70.

Figure 43-6. This patient presented with a large esophageal polyp protruding from her mouth following an episode of coughing. This polyp was found to originate from a narrow stalk in her cervical esophagus and was removed endoscopically. Of note, she had undergone operative resection of a cervical esophageal polyp earlier in life.

Figure 43-7. Relative change in incidence of esophageal adenocarcinoma and other malignancies (1975–2001). Data from the National Cancer Institute’s Surveillance, Epidemiology, and End Results program with age-adjustment using the 2000 U.S. standard population. Baseline was the average incidence between 1973 and 1975. *Blue line*, esophageal adenocarcinoma; *green line*, melanoma; *orange line*, prostate cancer; *yellow line*, breast cancer; *purple line*, lung cancer; *red line*, colorectal cancer. (Adapted with permission from Pohl H, Welch G. The role of overdiagnosis and reclassification in the marked increase of esophageal adenocarcinoma incidence. *J Natl Cancer Inst* 2005;97:142–146.)

Diagnosis and Staging

The vast majority of cases of esophageal cancer present late. The disease is largely asymptomatic due to the location of the tumor and clinical symptoms do not drive patient presentation until there is a significant degree of obstruction or bleeding. As a muscular conduit, the esophagus is quite accommodating until it is narrowed significantly. Up to 80% of patients present with dysphagia and 20% present with odynophagia. More subtle signs of a problem are often elicited retrospectively when questioning patients, where they admit to retrosternal discomfort and progressive symptoms that have been overlooked. When one investigates further, it is often discovered that the patient has altered their lifestyle or eating habits for a period of time. Typically patients have had difficulty with solids and then liquids as the tumor progresses. The vast majority of patients have significant weight loss on presentation and weight loss of more than 10% is a significant predictor of poor prognosis.⁴⁶

Patients may also present with significant pulmonary symptoms when there is a more advanced process leading to aspiration or there is direct airway invasion by a tumor. Direct airway invasion can occur with midesophageal tumors as the esophagus courses directly posterior to the left mainstem bronchus. New hoarseness is indicative of locally advanced tumor due to vocal cord paralysis. The Virchow node, a palpable left supraclavicular node, may be present in some patients. These findings are all indicators of poor prognosis and advanced disease.

The evaluation of a patient with suspected esophageal cancer involves a number of different tests which are aimed at accurate diagnosis and staging. This is extremely important as therapy decisions are made based on both of these findings. Barium swallow and esophagram are the mainstays of diagnosis for assessment of patients. Barium swallow obtains both anatomic and functional information. Flexible esophagoscopy is used to precisely locate the tumor, and biopsy can be performed to determine histology. In patients with a known tumor, important additional information can be obtained by EUS and this is considered the single most important test for determining T stage of the tumor. EUS

successfully predicts T stage in over 80% of cases when performed by an experienced endoscopist. Regional lymph nodes can also be visualized and sampled by FNA. This aids in determining the N stage. The sensitivity of EUS alone to predict N stage is 85% and increases to 95% when FNA is added.⁴⁷

At present there are no serum markers that have been found in esophageal cancer patients that would consistently yield meaningful clinical data. Standard serum cancer markers including CEA, CA19-9, and CA-125 have no value in the preoperative evaluation of the patient with esophageal cancer. The most useful laboratory parameters used clinically outside of a hemoglobin and electrolyte panel include nutritional parameters (albumin, prealbumin).

A CT scan of the chest, abdomen, and pelvis with contrast is a valuable tool for assessing tumor, lymph nodes, and the general anatomy related to the patient. Additionally, metastases to the liver and lung are assessed via this method. Positron emission tomography (PET) with 18F-fluorodeoxyglucose (FDG) is a physiologic unique test that detects metabolic activity within tissues. It is invaluable in the assessment and clinical staging of patients with esophageal cancer as it provides information on N and M stage to help guide clinical staging. PET scans are routinely obtained for the clinical staging of esophageal cancer patients prior to and after treatment to evaluate for disease and disease progression, respectively.

Additional staging modalities attempt to improve the accuracy of clinical staging. We use laparoscopic staging quite liberally in our practice. This allows us to perform endoscopy and bronchoscopy on every patient. In the laparoscopic staging procedure we can examine the extent of nodal involvement in the celiac lymph nodes and evaluate for local tumor advancement and any diaphragmatic invasion. Importantly, many patients present with significant dysphagia and weight loss, so nutritional needs can be addressed at the time of this procedure either with an esophageal stent or feeding jejunostomy. Finally, a chemotherapy port can be placed for easier access during treatment. We acknowledge that staging laparoscopy is not absolutely required, however we feel there are many advantages that it has to offer if planning further surgical intervention in the future.

Cervical Esophageal Cancer

Cancer of the cervical esophagus represents a very small subset of primary tumors. Direct extension into the esophagus by tumors of the thyroid and trachea are much more common. These tumors are challenging to treat and generally do not respond to surgical resection as a primary modality. Traditionally, chemoradiotherapy has been the standard treatment for these tumors. Those who get treated and have a good response may represent a small subset of patients that are referred esophagectomy with laryngectomy and tracheostomy.

Adenocarcinoma

5 Adenocarcinoma of the esophagus is the most common esophageal tumor in the United States and Western world, accounting for more than 50% of cases. The rise of this histologic subtype correlates with the incidence of gastroesophageal reflux disease (GERD) and obesity in the Western world, and the overall prevalence of BE appears to be rising within the West. Whether this finding is related to a true increased incidence or heightened surveillance is not clear. Although the overall incidence of BE is unknown, autopsy series have estimated the prevalence to be 376 cases per 100,000 in Olmsted County, MN, USA.⁴⁸ Remarkably, this rate is five times the clinical prevalence in the same geographic area (82.6 per 100,000). As a result of findings such as these, it is generally well accepted that the subclinical prevalence is underestimated. These cohort studies suggest that the majority of patients with BE are undiagnosed because they experience minimal to no symptoms.

The sequence leading from chronic GERD to the development of Barrett esophagus, the precursor of adenocarcinoma of the esophagus, is well defined. The esophagus is normally lined by squamous mucosa, and repeated injury from chronic reflux leads to transformation of the normal squamous mucosa into columnar epithelium. This is likely a two-step process, with the first step involving the transformation of normal esophageal squamous mucosa to simple columnar epithelium. This initial step takes place relatively quickly over the course of a few years, while the second step, the development of intestinal metaplasia, proceeds over 5 to 10 years.⁴⁹ Once present, Barrett can progress to low-grade and high-grade dysplasia. With progression to dysplasia, the nuclei become more crowded and the normal glandular architecture is lost. Patients with high-grade dysplasia carry a significant risk of the development of adenocarcinoma, and at 5 years 10% to 30% of patients will develop invasive findings. The annual rate of neoplastic transformation is 0.5%.⁵⁰ Patients with recurring symptoms of reflux have an eightfold increase in the risk of adenocarcinoma. Patients with nondysplastic Barrett's have a 0.5% per patient-year rate of progression to esophageal adenocarcinoma.^{51,52} At the time of esophagectomy

for high-grade dysplasia, invasive carcinoma is identified in as many as 30% to 40% of patients.⁵³

Squamous Cell Carcinoma

Squamous cell carcinoma is more frequent world wide with the primary risk factor for development being chronic irritation of the esophageal mucosa. This is hypothesized to be associated most frequently with prolonged alcohol consumption which is believed to be enhanced with concomitant tobacco exposure. Nitrosamines and other nitrosyl compounds found in smoked meats are especially important carcinogens that the native populations rely on heavily. Hot beverages in Asian countries have been theorized to be associated with a high incidence. Medical conditions such as achalasia, caustic strictures, Plummer–Vinson syndrome, and tylosis also increase the risk of incidence. The risk with long-standing achalasia is in the range of 5% to 7%, thus surveillance with biopsies is recommended in these patients.⁵⁴

Staging

In 2009, the American Joint Committee on Cancer (AJCC) published the seventh edition AJCC Cancer Staging Manual. Table 43-4 summarizes the seventh edition AJCC TNM system for staging esophageal cancers. This new staging system has significant revisions from the previous sixth edition which are summarized in Table 43-5. Several stages and categories are redefined and subclassified. Tumors arising in the stomach less or equal to 5 cm away from the esophagogastric (EG) junction and tumors arising from or crossing the EG junction are all staged under this new system. The stage groupings have all been reassigned, with the new pathologic stage relying all on the number of nodes containing metastasis, tumor grade, tumor location, and histologic cell type in the seventh edition staging criteria. The revised staging groupings and current recommended treatment strategies for each stage are displayed in Table 43-6.

The importance of a cancer staging protocol lies in the strong association between stage of the disease and outcomes. The seventh edition AJCC TNM staging system is data driven and harmonized. It will allow physicians to clinical stage esophageal cancers accurately, which is of paramount importance during the formulation of an appropriate treatment plan. Preoperative evaluation is necessary to identify the extent of disease and help elicit the clinical stage. CT scans of the chest and abdomen are crucial to preoperative evaluation and should be ordered in all patients. We also recommend PET scanning in conjunction with CT imaging to detect distant metastatic disease. In the absence of liver, lung, or other distant metastatic disease, esophageal ultrasound should be used to assess regional lymph nodes and define the depth of tumor invasion. Patients with stage-appropriate disease should be optimized from a medical standpoint prior to undergoing resection.

Table 43-4 T, N, and M Status and Histologic Grade Definitions for Esophagus and Esophagogastric Junction Cancer in the Seventh Edition of the American Joint Committee on Cancer (AJCC) Cancer Staging Manual

T status	
Tis	High-grade dysplasia
T1	Invasion into the lamina propria, muscularis mucosae, or submucosa
T2	Invasion into muscularis propria
T3	Invasion into adventitia
T4a	Invades resectable adjacent structures (pleura, pericardium, diaphragm)
T4b	Invades unresectable adjacent structures (aorta, vertebral body, trachea)
N status	
N0	No regional lymph node metastases
N1	1–2 positive regional lymph nodes
N2	3–6 positive regional lymph nodes
N3	7 or more positive regional lymph nodes
M status	
M0	No distant metastases
M1	Distant metastases
Histologic grade	
G1	Well differentiated
G2	Moderately differentiated
G3	Poorly differentiated
G4	Undifferentiated

Neoadjuvant Therapy

The current information on neoadjuvant treatment can be divided into studies evaluating preoperative radiation, preoperative chemotherapy, and combined preoperative chemoradiation therapy. In operable patients with resectable tumors, the results of any preoperative therapy followed by resection must be compared with the results of primary resection alone. It is important that this analysis takes into account the toxicities associated with multimodality therapy and the impact on the intended resection and quality of life. Several randomized trials have failed to show any benefit from preoperative radiation therapy alone. Proponents of preoperative radiotherapy argue that the trials are too small to demonstrate the advantages of this approach. A meta-analysis of available randomized trials comprising 1,147 patients, however, found no improvement in survival with preoperative radiotherapy alone in patients with resectable esophageal cancer.⁵⁵ At this time, there is no indication for preoperative radiation therapy alone followed by resection.

Table 43-5 Summary of Changes from AJCC Sixth to Seventh Edition Esophagus and Esophagogastric Junction Cancers Staging System

- Tumor location is simplified, and esophagogastric junction and proximal 5 cm of stomach are included.
- Tis is redefined and T4 is subclassified.
- Regional lymph nodes are redefined. N is subclassified according to the number of regional lymph nodes containing metastasis.
- M is redefined.
- Separate stage groupings for squamous cell carcinoma and adenocarcinoma.
- Stage groupings are reassigned using T, N, M, and G classifications.

Table 43-6 American Joint Committee on Cancer (AJCC) Stage Groupings with Recommended Treatment and 5-Year Survival

Stage	TNM Designation	Treatment	5-Yr Survival (%)
0	Tis, N0, M0, G1	Surgery alone	N/A
IA	T1, N0, M0, G1–2	Surgery alone	87.7
IB	T1, N0, M0, G3 T2, N0, M0, G1–2	Surgery alone	73.3
IIA	T2, N0, M0, G3	Surgery alone	55.3
IIB	T3, N0, M0, G-any T1–2, N1, M0, G-any	Surgery or neoadjuvant treatment followed by surgery	40.1
IIIA	T1–2, N2, M0, G-any T3, N1, M0, G-any T4a, N0, M0, G-any	Surgery or neoadjuvant treatment followed by surgery	24.3
IIIB	T3, N2, M0, G-any	ChemoXRT	11.9
IIIC	T4a, N1–2, M0, G-any T4b, N-any, M0, G-any T-any, N3, M0, G-any	ChemoXRT	3.1
IV	T-any, N-any, M1, G-any	Palliation (chemo, XRT, stenting, or combination)	0.0

The utility of preoperative chemotherapy alone is much more poorly defined. A large multicenter randomized trial in the United States (Intergroup Trial) of 440 patients failed to show any improvement in survival after three cycles of combined cisplatin and fluorouracil followed by surgery and two postoperative cycles when compared to surgery alone.⁵⁶ This is in contrast to a large randomized European study (Medical Research Council), which suggested that neoadjuvant chemotherapy resulted in nearly a 10% improvement in survival at 2 years.⁵⁷ Unfortunately, the preoperative staging techniques and duration of treatments were quite different, making the two studies difficult to compare. More recently, another European neoadjuvant chemotherapy trial (MAGIC trial) demonstrated improved survival with perioperative chemotherapy versus surgery alone (36% vs. 23% at 5 years).⁵⁸ Of note, 75% of the MAGIC trial participants had gastric cancer. Also, only 41.6% of patients randomized to perioperative chemotherapy were able to complete all six prescribed cycles of therapy. In a recent Cochrane review of the topic, 11 randomized controlled trials with 2,051 patients suggested that preoperative chemotherapy plus surgery may offer a survival advantage compared to surgery alone for resectable esophageal cancer.⁵⁹ There was no demonstrable difference in the rate of resection, tumor recurrence, or postoperative morbidity. There was some chemotherapy-related morbidity. Presumably based on the relative success of the MRC and MAGIC trials, chemotherapy alone is used quite commonly as neoadjuvant therapy in Europe, whereas combined chemotherapy and radiation is used more commonly in the United States. Several small randomized trials have evaluated combined preoperative chemoradiation followed by surgical resection. The most widely cited trial to justify the use of combined treatment followed by surgery was published by Walsh et al. in 1996.⁶⁰ This study projected a 3-year survival of 32% in the neoadjuvant treatment group as compared to 6% in the surgery alone group for patients with adenocarcinoma. Critics were quick to point out the lack of appropriate staging, the poor survival in the surgical group as compared with other surgical series, and the small study size. A more recent study found equivalent median and 3-year survival in patients with squamous cell carcinoma of the esophagus randomized to either preoperative chemoradiation followed by surgery or surgery alone.⁶¹ An increased complication rate was noted in the patients undergoing preoperative chemoradiation therapy. A recent metaanalysis of 10 randomized controlled trials of neoadjuvant chemoradiotherapy versus surgery alone demonstrated an absolute survival advantage of 13% at 2 years favoring neoadjuvant therapy.⁶² Despite a paucity of conclusive data, there seems to be an evolving consensus at most centers that patients with T3 and/or N1 disease should receive neoadjuvant chemoradiation. This issue remains unresolved, and operation remains the standard treatment for localized esophageal cancer outside of a clinical trial. At this time we consider neoadjuvant chemoradiotherapy to be investigational. Unfortunately, a large intergroup trial designed to answer this question was closed because of poor accrual.

More recently, the CROSS Trial enrolled 363 patients from the Netherlands, of which 75% had GE junction adenocarcinoma.⁶³ They were randomized to chemotherapy with concurrent XRT (41.4 Gy) then surgery versus upfront surgery. Improved survival was seen in the neoadjuvant group at 5 years suggesting that chemoradiotherapy followed by surgery provided a survival advantage. Both arms in the trial were noted to have an unusually high leak rate related to surgery (CRT 22% vs. surgery 30%). This called into question the validity of the surgical standardization in the operative approach as this leak rate is quite high. The long-term results (minimum 5-year follow-up) were recently reported and confirmed the overall survival benefits for neoadjuvant chemoradiotherapy when added to surgery (43

months vs. 27 months, $p < 0.03$) in patients with resectable esophageal or EG junctional cancer.⁶⁴

6 Recently the Society of Thoracic Surgeons released a consensus statement on neoadjuvant therapy for the treatment of esophageal cancer stating the following class IIA recommendations based on level A evidence⁶⁵:

1. “Neoadjuvant platinum-based doublet chemotherapy alone is beneficial before resection for patients with locally advanced esophageal adenocarcinoma.”
2. “Neoadjuvant chemoradiotherapy should be used for locally advanced squamous cell cancer and either neoadjuvant chemotherapy or chemoradiotherapy for locally advanced adenocarcinoma as multimodality therapy has advantages over operation alone.”

SURGICAL CONSIDERATIONS IN APPROACHING THE ESOPHAGUS

The esophagus is generally considered one of the most problematic organs to manage when it comes to the indication for operation, patient fitness, operative approach, and the postoperative consequences of complications. There is no doubt that surgical experience and expertise play a critical role in all phases of esophageal disease ending up in the operating room.

A complete working knowledge of the anatomical relationships between the esophagus and adjacent structures is vital. We feel it is a requirement and marked advantage for those formally trained in general thoracic surgery to be the ones performing these operations. The upper esophagus is in contact with the posterior membranous trachea, the left mainstem bronchus, and the aortic arch. Patients with cancers involving the upper thoracic esophagus must undergo preoperative bronchoscopy to rule out involvement of the airway as this generally precludes safe resection.

From a surgical perspective the esophagus is divided into thirds. The upper third can be reached through a cervical incision. The middle third is best approached through the right chest as access through the left chest is limited by the aortic arch. The distal third of the esophagus is best approached through the left chest. The short segment of intra-abdominal esophagus may be approached through the upper abdomen.

7 When esophagectomy is required, several surgical approaches have been described. Generally speaking, no one surgical approach fits all. These approaches include the transhiatal approach,⁶⁶ transabdominal transthoracic approach (Ivor Lewis),⁶⁷ the three-stage or “three-field” approach (McKeown),⁶⁸ and the thoracoabdominal approach.^{69,70} In the current era, both minimally invasive and robotic approaches have been championed and our group has led pioneering efforts in this regard. Each approach has its own set of risks and benefits as well as clear opinions on those merits. Our belief is that selection of the approach should be coupled with surgical expertise and patient pathology. Generally speaking, several studies have shown equivalent outcomes when it comes to removal of the esophagus and one trades one variable for another when critically evaluating the results. Careful review of the literature draws on two important variables: surgeon experience and volume.⁷¹ Failures in technique that occur during the performance of esophagectomy are associated with increased length of stay, in-hospital mortality, and poorer overall long-term survival.⁷²

OPERATIVE MANAGEMENT

Approaches to Esophagectomy

There are several surgical approaches to esophagectomy and the master esophageal surgeon should be familiar with all approaches as they have different indications depending on the individual patient, the location of the tumor, and surgeon experience. Options for reconstruction include a gastric tube, colonic interposition, and in selected small cases an intestinal free graft. We opt for the use of colon or small bowel in patients where the stomach is not usable because of the morbidity associated with these conduits. The highlights of the main approaches will be presented along with an in-depth description of the approach to minimally invasive esophagectomy (MIE) to help outline the critical considerations for the steps of the operation.

Transhiatal Esophagectomy

Mark Orringer has championed this approach for esophagectomy with outstanding results and leak rates

in the 3% to 5% range.⁷³ The procedure starts with an upper midline laparotomy and left cervical incision as shown in [Figure 43-8](#). A gastric conduit based on the right gastroepiploic artery is used to establish gastrointestinal continuity. A modified stapled anastomosis is performed to complete the EG anastomosis ([Fig. 43-9](#)).

Many surgeons prefer THE in the current era, as historically it has been compared to open Ivor Lewis esophagectomy. Debate continues over the effectiveness of it as a cancer operation, as thoracic lymphadenectomy is not a part of the procedure as seen in the Ivor Lewis Approach. Proponents for the operation argue that the approach has lower morbidity and mortality than the Ivor Lewis approach. Should a leak occur in the neck, it can be treated by simple bedside cervical drainage. A leak in the chest following the Ivor Lewis approach is far more likely to result in severe mediastinitis and other significant complications. The arguments and debates are certainly quite different in the current era with the excitement surrounding MIE.

Ivor Lewis Esophagectomy

The transabdominal transthoracic approach to esophagectomy as initially described is more commonly referred to as the Ivor Lewis esophagectomy. The specific steps are covered in the section on MIE as we perform this operation through minimal access surgery. Following laparotomy and creation of the gastric conduit, the stomach is mobilized and a posterolateral thoracotomy is performed through the 5th interspace. The intrathoracic esophagus is mobilized under direct vision and the EG anastomosis is performed at the level of the azygos vein. This approach is especially useful for bulky tumors or where there are concerns regarding airway injury. As discussed above, critics of this approach point out the increased morbidity of the operation and the potential perils of a chest anastomosis. The lymphadenectomy is clearly superior with this approach and the risk of local recurrence, in theory, reduced.

Three-Field Esophagectomy

This approach is carried out through a separate laparotomy, thoracotomy, and left cervical incision.⁶⁸ The anastomosis is performed in the neck. This approach is appropriate for mid-esophageal tumors where there is concern of airway injury during the dissection. Another potential advantage is a three-field lymphadenectomy. In summary, the operation has the potential to provide the patient with a more complete resection and thus improves long-term survival. This claim has not been overtly substantiated in the literature.

Thoracoabdominal Approach

The left thoracoabdominal approach is the least frequently used of all the approaches to the esophagus. It is performed by making an oblique incision from the midpoint between the xiphoid and the umbilicus across the costal arch to the tip of the scapula. The abdomen is opened and the diaphragm divided along the chest wall to spare any phrenic nerve branches. This approach is sometimes useful in those patients who have had hiatal work done previously. For patients with distal tumors and inadequate conduit for esophageal replacement, the anastomosis can be made in the left chest just below the inferior pulmonary vein. For those with adequate conduit, the esophagus can be mobilized and a left cervical anastomosis can be performed. The morbidity of this approach is quite high, however the largest series of 64 patients reported no anastomotic leaks and 2% mortality.⁷⁴

Figure 43-8. A: Transhiatal mobilization of the thoracic esophagus from the posterior mediastinum with the use of blunt dissection and traction on rubber drains placed around the esophagogastric junction and cervical esophagus. The volar aspects of the fingers are kept against the esophagus to reduce the risk for injury to adjacent structures. B: Lateral view showing transhiatal mobilization of the esophagus away from the prevertebral fascia. Half of a sponge on a stick is inserted through the cervical incision and advanced until it makes contact with the hand inserted from below through the diaphragmatic hiatus. Arterial pressure is monitored as the heart is displaced forward by the hand in the posterior mediastinum.

Figure 43-9. The stapled technique for cervical esophageal anastomosis. This technique results in lower anastomotic leak rates and fewer postoperative strictures.

Minimally Invasive Esophagectomy

Some surgeons have combined a thoracoscopic approach with a laparotomy, while others reported a laparoscopic abdominal component with an open thoracotomy for the chest. While these hybrid operations do fall under the umbrella of minimally invasive esophageal resection, a strict definition of minimally invasive esophageal resection avoids both a thoracotomy and a laparotomy completely. In our experience, we initially started with a laparoscopic transhiatal approach (in 15 patients) and attempted to reach our finger dissection from the neck incision. We found this to be quite difficult in most patients. We then converted to a combined thoracoscopic/laparoscopic approach with a neck

anastomosis, as it afforded better visualization of the periesophageal structures especially near the main airways and subcarinal areas, was less affected by patient height and body habitus, improved our ability to do a more complete nodal dissection, and greatly improved overall visualization compared with the totally laparoscopic method. This minimally invasive three-field (McKeown approach) operation was our procedure of choice for 6 to 8 years (approximately 500 cases). Following this extensive minimally invasive experience, we moved to a minimally invasive Ivor Lewis approach in which we start laparoscopically and complete using a right thoracoscopic approach and a high thoracic anastomosis. We prefer this approach because the avoidance of a neck dissection essentially eliminates recurrent laryngeal nerve injury. Additionally, minimally invasive Ivor Lewis resection allows a more aggressive gastric resection margin; amputation of the most proximal tip of the newly constructed gastric conduit, which is the most susceptible to ischemia and potential leak; and performance of the anastomosis with a wide view within the chest cavity.^{75,76}

8 In 2000, Nguyen et al. compared MIE with open transthoracic esophagectomy and transhiatal esophagectomy (THE). Shorter operative times, less blood loss, and shorter stays in the ICU with no increase in morbidity were documented with the minimally invasive approach as compared with the open approach. Over the past several years, several series have been published on minimally invasive resections that demonstrate comparable survival outcomes compared with large open series.⁷⁷

Indications for the minimally invasive approach for esophagectomy include Barrett esophagus with high-grade dysplasia, end-stage achalasia, esophageal strictures, and esophageal cancer. While most T4 esophageal cancers are generally not amenable to open or minimally invasive surgical approaches, cancers of all other T stages are potentially amenable to MIE in experienced hands. Esophageal cancer that has been downstaged after neoadjuvant chemoradiation is also potentially resectable by a minimally invasive approach but, as with open operations in this setting, can be technically more difficult than nonirradiated fields. Previous thoracic and abdominal surgery is not necessarily a contraindication to MIE depending on the extent of the previous surgery and the experience of the surgeon. The minimally invasive Ivor Lewis esophagectomy works well for most distal esophageal cancers, short-to-moderate length Barrett with high-grade dysplasia, and gastroesophageal junction tumors extending onto the gastric cardia. Total laparoscopic and thoracoscopic Ivor Lewis resections should not be performed for upper third esophageal cancers with significant proximal extension due to concern for adequate margins of resection. Some midesophageal tumors can be approached with the Ivor Lewis technique, but a very high intrathoracic anastomosis may be needed to gain a negative margin.

Anesthetic Considerations

Anesthetic management during MIE poses specific challenges. Whereas all patients receive an arterial blood pressure monitoring line, central venous catheter placement is not routine. A double-lumen endotracheal tube is placed initially in anticipation of the thoracoscopic phase. In patients with midthoracic or upper thoracic tumors, a single-lumen endotracheal tube is initially placed for preoperative bronchoscopy to evaluate airway involvement.

Patients generally require significant volume loading during the laparoscopic phase secondary to the pneumoperitoneum and steep reverse Trendelenburg positioning. Given the high flow of CO₂ required, the patient can develop significant hypercarbia and acidosis. The surgeon must also be mindful of vasopressors administered by the anesthesiologist because these agents directly affect the viability of the newly created gastric conduit. Simple measures can be undertaken to help correct these problems. Maneuvers to increase preload include lowering the insufflation pressure, decreasing the degree of the reverse Trendelenburg position, and increasing volume loading. In addition to changes in the ventilator settings, hypercarbia can often be corrected by reversing the pneumoperitoneum, allowing the patient time to compensate and clear the excess CO₂. There must be clear and ongoing communication throughout the procedure between the surgeon and the anesthesiologist.

Endoscopic Evaluation

The operation begins with a careful EGD. The location of the tumor is confirmed along with precise measurements of the proximal and distal extent of the lesion. The surrounding esophagus is examined for evidence of Barrett changes proximal to the intended resection margin, with four-quadrant biopsies taken in areas of clinical concern. Careful endoscopic examination of the stomach is also imperative to assess its suitability for use as a conduit in esophageal reconstruction. Air insufflation should be kept to a minimum during the examination to reduce the degree of small bowel distention which may

significantly decrease domain and heighten the difficulty of laparoscopy.

Laparoscopic Phase

Positioning and Laparoscopic Port Placement

The patient is positioned supine with the arms out at 60 degrees. A foot board is placed to allow steep reverse Trendelenburg positioning during the hiatal dissection. The costal margin is identified and a line is drawn from the xiphoid to the umbilicus. This line is then divided into thirds. The first port is placed using a direct Hasson cutdown approach in the right paramedian position roughly 2 cm lateral to the midline at the junction of the lower and middle thirds of the described line. A total of five abdominal ports are used for gastric mobilization (12-mm right and left paramedian, 5-mm right and left subcostal, and a second 5-mm right lateral subcostal port for liver retraction ([Fig. 43-10](#)) with the remaining ports placed under direct laparoscopic vision. A sixth port is placed in the right paraumbilical region to assist in placement of the feeding jejunostomy tube. All ports should be a hand's breadth apart so as to avoid interference between instruments. In addition, it is important to keep skin and fascial incisions small so as to avoid subcutaneous emphysema.

While working at the hiatus, the camera is placed in the left paramedian port position. The surgeon works from the right side of the table using the right paramedian and subcostal ports. The assistant, on the left of the table, controls the camera as well as a second grasper for retraction (through the left subcostal port). The liver retractor is brought in through the right lateral subcostal port and positioned to elevate the left lobe of the liver and expose the hiatus.

Figure 43-10. Laparoscopic port placement. The 10-mm port is placed first in the right midabdomen using open Hasson trocar insertion technique. An additional 5/11-mm port is placed in the right lower quadrant that is helpful for retraction during pyloroplasty and gastric tube creation.

Gastric Mobilization

Thorough inspection of the abdomen is performed to ensure that no injuries were caused during the process of port placement and to evaluate for intraperitoneal metastasis. The peritoneal lining, omentum, and liver are visually inspected for abnormalities with biopsies taken of any suspicious lesions for frozen-section evaluation. The gastrohepatic ligament is opened and the left gastric vascular pedicle identified ([Fig. 43-11](#)). A complete lymph node dissection is then performed, leaving the left gastric and celiac lymph nodes with the specimen. This dissection is continued laterally along the splenic artery and the superior border of the pancreas and superiorly toward the crura along the preaortic plane. If there is a question of potential malignant involvement, these nodes are sent for frozen-section evaluation to aid in determination of resectability. Once ensured that no nodal disease is present, the right crus is dissected, allowing lateral mobilization of the esophagus. This dissection is continued anterior to the esophagus, transecting the phrenoesophageal ligaments and exposing the anterior hiatus. The left crus may be exposed either by the continuation of this anterior dissection along the medial crural border or by first mobilizing the fundus of the stomach by division of the short gastric vessels. Dissection of the left crus is continued posteriorly until the decussation of the right and left crural fibers is noted. This exposes the retroesophageal window and ensures complete mobilization of the superior

portion of the lesser curvature and gastroesophageal junction.

After identifying the gastrocolic omentum, the antrum of the stomach is retracted, and a window is created in the greater omentum, thus allowing access to the lesser sac. The remaining short gastric vessels are divided, taking care to preserve the right gastroepiploic arcade. The fundus is retracted to the right and this dissection is continued posteriorly, eventually exposing the left gastric artery and vein and joining the lesser curve dissection plane to complete mobilization of the stomach. Gastric mobilization is carried inferiorly to the pyloroantral region. Meticulous attention must be paid during this phase of the dissection because any injury to the gastroepiploic arcade at this level may render the gastric conduit unusable. This dissection may be especially difficult in patients who have had pancreatitis or a history of prior biliary surgery. Adequate mobilization has been achieved when the pylorus is able to reach the level of the caudate lobe of the liver, which may require either a partial or a complete Kocher maneuver. The left gastric artery and vein are then divided using an endovascular GIA stapler. Care should be taken to ensure that all nodes are swept toward the specimen side and to avoid narrowing of the splenic or hepatic arteries.

Creation of the Gastric Tube

The gastric tube is created prior to the completion of the pyloroplasty and placement of the feeding jejunostomy tube to allow for an assessment of the viability of the gastric conduit. The gastric tube follows the arc of the greater curve of the stomach and is based on the right gastroepiploic artery (Fig. 43-12). An endovascular stapling technique allows for a controlled creation of the gastric tube conduit. The first staple load is placed across the adipose tissue and vessels along the lesser curve, above the level of the right gastric artery. No stomach is divided in this initial staple firing, which is intended to provide hemostasis. The subsequent staple firings divide the stomach. We prefer 45-mm staple loads for this process (purple loads; Endo GIA Reloads with Tri-staple Technology, Covidien, Mansfield, MA) because the course of the greater curvature can be followed more precisely, resulting in improved conduit length. An additional grasper is brought through the right paraumbilical port at this time to assist in the retraction of the stomach during creation of the gastric tube. It is important to keep the stomach on stretch during this process so as to create a straight conduit. The first assistant grasps the tip of the fundus along the greater curve and gently stretches it toward the spleen. A second instrument from the paraumbilical port grasps the antral area with a slight downward retraction. The stomach is first horizontally divided across the antrum. The staple line is then directed superiorly, toward the fundus, parallel to the line of the greater curve. A conduit width of 4 to 5 cm is preserved (Fig. 43-13). The length of the conduit is shortened if there is concern for extension of the tumor onto the gastric cardia. Sutures may be placed to reinforce the staple line if there is concern about its integrity, although this practice is not routinely necessary.

Figure 43-11. Laparoscopic staging, with opening of the gastrohepatic ligament and evaluation of left gastric/celiac lymph nodes.

Figure 43-12. Creation of gastric conduit. The first stapler along the lesser curve is a vascular endo GIA stapler after which the thick antrum is divided with the 4.8 mm (green) loads that are 45 mm long fired sequentially. The antrum and the fundus are pulled in opposite direction to provide adequate tension during the gastric conduit creation.

Pyloroplasty

The pylorus is visually identified and 2-0 Surgidac (Covidien, Mansfield, MA) stay sutures are placed on the superior and inferior aspects using the Endostitch device (U.S. Surgical, Norwalk, CT) to place it on stretch (Fig. 43-14). The anterior wall of the pylorus is then transected with ultrasonic shears. The pyloromyotomy is then closed transversely in a Heineke–Mikulicz fashion using simple, interrupted 2-0 Surgidac sutures. An omental patch (with a vascular pedicle if the patient received neoadjuvant treatment) is placed over the pyloroplasty prior to termination of the abdominal portion of the operation.

Figure 43-13. Completed gastric conduit with an intact right gastroepiploic arcade and an intact right gastric artery.

Figure 43-14. Creation of pyloroplasty (A) and vertical closure (B) in a Heineke–Mikulicz fashion.

Feeding Jejunostomy Tube Placement

A 10-French jejunostomy catheter is placed in the left lower quadrant using a percutaneous technique (Fig. 43-15). The transverse colon is retracted superiorly to expose the ligament of Treitz and a position in the jejunum is identified 30 to 40 cm from this location. The antimesenteric border of the bowel is sutured to the abdominal wall with a 2-0 Surgidac suture. The 12-mm right paraumbilical port is used by the surgeon with the camera positioned in the right paramedian location. A Seldinger technique is then used to introduce the catheter into the jejunum under direct laparoscopic vision. Air insufflation via the catheter can be used to verify luminal placement. The jejunum is then tacked to the abdominal wall anterior to the catheter entry site to prevent leakage, and an additional suture to the abdominal wall is placed in the distal limb of jejunum to prevent rotation and obstruction.

Preparation for Thoracoscopic Phase

The gastric conduit is again assessed for viability and, if needed, resection of the nonviable portion and further mobilization with extension of the Kocher maneuver are performed at this time. Once viability of the conduit is ensured, the most superior portion of the gastric tube is stitched to the specimen (Fig. 43-16). It is imperative to maintain the alignment of the conduit so that twisting is avoided as the stomach is brought into the chest. We ensure this by suturing the greater curvature along the short gastric vessels to the staple line of the proximal gastric remnant. If an omental flap has been created, the distal end is sutured to the conduit tip. Clips are applied to the staple line as needed for hemostasis. The specimen and gastric conduit are then placed in the lower mediastinum, again taking care to preserve the proper orientation of the gastric conduit (Fig. 43-17). If the hiatal opening appears large, the crura are reapproximated with a stitch to prevent delayed thoracic herniation of the conduit. A nasogastric tube is then placed in the esophagus for decompression in preparation for the thoracic phase of the operation.

Thoracoscopic Phase

Positioning and Port Placement

Turn the patient to the left lateral decubitus position and reconfirm placement of the double-lumen endotracheal tube. The operating surgeon stands on the right side of the table (facing the patient's back) while the assistant stands on the left side of the table. A total of five thoracoscopic ports are used (Fig. 43-18). A 10-mm camera port is placed in the eighth or ninth intercostal space, just anterior to the midaxillary line. The working port is a 10-mm port placed in the eighth or ninth intercostal space, posterior to the posterior axillary line. Another 10-mm port is placed in the anterior axillary line at the fourth intercostal space, through which a fan-shaped retractor aids in retracting the lung to expose the esophagus. A 5-mm port is placed just inferior to the tip of the scapula for the surgeon's left hand. A final 5-mm port is placed at the sixth rib, at the anterior axillary line for suction by the assistant.

Thoracoscopic Dissection and Resection of the Esophagogastric Specimen

Adequate retraction of the diaphragm is essential to the thoracoscopic phase of the dissection. A 48-in, 0 Surgidac suture is placed through the central tendon of the diaphragm using the Endostitch. The suture is brought out through the lateral chest wall at the level of the insertion of the diaphragm through a small stab incision, retracting the diaphragm inferiorly and exposing the distal esophagus. The inferior pulmonary ligament is divided to the level of the inferior pulmonary vein to allow for maximal retraction to the lung. This dissection is carried onto the avascular plane along the surface of the pericardium, which becomes the medial border of the dissection. This dissection is carried superiorly to the subcarinal space, with the lymph nodes kept en bloc with the esophagus (Fig. 43-19). Care must be taken to identify the membranous wall of the right mainstem bronchus because it is easily injured during this phase of the dissection. Removing any suction from the right lung during this dissection will prevent the membranous wall from collapsing and can aid in visualization. The lung is then retracted anteriorly and the pleura incised along the anterior border of the esophagus to the level of the azygos vein. The azygos vein and vagus nerve are divided to facilitate the dissection and prevent traction injuries to the recurrent laryngeal nerve during esophageal mobilization. Above the level of the azygos vein, dissection is kept close to the esophagus to avoid injury to the recurrent nerves. The extent of superior dissection and mobilization depends upon the location of the tumor and the intended site of resection. To facilitate lateral mobilization, the pleura is divided in the groove posterior to the esophagus. This dissection is kept superficial to avoid injury to the thoracic duct and underlying thoracic aorta. Bridging lymphatics and aortoesophageal vessels are controlled with endoclips and subsequently divided with the ultrasonic shears. A careful thoracic duct ligation should be considered if there is

concern for trauma to the duct. This lateral dissection is carried along the length of the esophagus from above the azygos vein to the level of the gastroesophageal junction. The contralateral pleura marks the deep margin of the dissection. The left pleural space may be entered if needed to remove a bulky tumor. The insertion of a Penrose drain to encircle the esophagus can also be useful to provide traction and elevate the esophagus from the mediastinal bed.

Figure 43-15. Placement of a 10-French needle jejunostomy catheter and an antitorsion stitch 3 to 4 cm distally along the antimesenteric border.

Figure 43-16. The gastric conduit is secured to the specimen along the lesser curve staple line for proper orientation during the thoracoscopic portion with a horizontal U stitch.

Figure 43-17. Proper orientation of the gastric conduit during the thoracoscopic part.

Once the esophagus has been completely mobilized, the specimen and attached gastric conduit are delivered into the chest, preserving the orientation of the gastric tube. The conduit staple line should be directly facing the lateral chest wall. The stitch between the specimen and the conduit is cut and the tip

of the conduit secured to the diaphragm with an Endostitch to prevent it from retracting into the abdomen. The specimen is then retracted anteriorly and superiorly, away from the esophageal bed, and the dissection completed along the contralateral pleural surface. Above the level of the azygos vein, this dissection again moves to the plane along the wall of the esophagus itself to avoid recurrent laryngeal nerve injury. Lymph node sampling is not routinely performed at this level.

Once mobilization of the esophagus is complete, a 4- to 5-cm minithoracotomy is made between the surgeon's working port and the tip of the scapula. A wound retractor (Applied Medical, Rancho Santa Margarita, CA) is placed to protect the skin and chest wall. The esophagus is then sharply transected using laparoscopic scissors at or above the level of the azygos vein as determined by the proximal extent of tumor. The nasogastric tube is pulled back into the proximal esophagus under direct vision as this is done. The esophagogastrectomy specimen is then withdrawn through the wound protector and sent for frozen section evaluation of the resection margins.

Creation of the Gastroesophageal Anastomosis

Attention is next turned to construction of the EG anastomosis. Our preferred technique utilizes an end-to-end anastomosis (EEA) stapling device (Fig. 43-20). The anvil of the stapler is placed in the cut proximal end of the esophagus and secured in place with two pursestring sutures of 2-0 Surgidac. All layers of the esophagus must be included in the suture to ensure a competent anastomosis. Typically, a 28-mm EEA stapler can be used without difficulty. This size will help to minimize stricture formation and potentially decreases the need for postoperative dilation. If the proximal esophagus does not appear large enough to accommodate the 28-mm anvil, a Foley catheter can be used to gently dilate the esophageal lumen in an attempt to facilitate placement of the anvil before electing a smaller stapler size. The gastric conduit is pulled further into the chest and the tip of the gastric conduit is opened using ultrasonic shears to the right side of the staple line. The EEA stapler is placed through the wound protector and positioned through the gastrotomy inside the conduit. The stapler spike is brought out along the greater curve of the gastric conduit to dock with the anvil. Prior to creating the anastomosis, we carefully estimate the amount of conduit that will lie in the chest. It is a common mistake to bring an excess stomach into the chest with the intent of minimizing tension on the anastomosis. A redundant conduit above the diaphragm can lead to significant problems with conduit emptying. In addition, ensuring proper orientation of the stomach is critical to prevent twisting. The stapler is then opened two complete turns and withdrawn. The tissue rings are inspected to ensure that they are complete prior to proceeding further.

Figure 43-18. Thoracoscopic port placement.

After stapling, the remaining excess gastric tip, including the gastrotomy through which the stapler was introduced, is resected with two or three loads of the endovascular GIA stapler (Fig. 43-21). If an omental flap was created during the abdominal dissection, it is wrapped around the anastomosis and secured in place with two or three sutures. The chest is then thoroughly irrigated and inspected for hemostasis. Final anatomy of the reconstruction is demonstrated in Figure 43-22.

Figure 43-19. Thoracoscopic esophageal mobilization. The lung is retracted anteriorly and the pleura along the esophagus is excised. The subcarinal lymph nodes are excised en bloc along with the specimen.

Drain Placement and Closure

Adequate drainage of the mediastinum and the area surrounding the anastomosis is imperative to mitigate complications related to anastomotic leak. A 10-mm Jackson–Pratt drain is placed posteriorly along the anastomosis and a 28-French chest tube is directed posteriorly toward the apex. The previously placed nasogastric tube is advanced past the anastomosis under thoracoscopic visualization. The gastric conduit is sutured to the right crus with a single 2-0 Endostitch to prevent torsion or delayed herniation of the conduit. A long aspirating needle is used to instill a multilevel intercostal nerve block to aid in postoperative pain control. The minithoracotomy is closed using pericostal sutures with a multilayer soft tissue closure. The Jackson–Pratt drain is secured with multiple sutures to prevent it from becoming dislodged. Once the patient is turned to the supine position, the oropharynx and nasopharynx are suctioned free of all secretions. The double-lumen endotracheal tube is withdrawn and the patient reintubated with a single-lumen endotracheal tube. Use of a tube exchange catheter should be discouraged because this device is placed blindly and may cause injury to the right mainstem bronchus, which is potentially vulnerable owing to the dissection of the thoracic esophagus. A toilet bronchoscopy is then performed using an adult bronchoscope. At this time, both right and left mainstem bronchi are examined for any evidence of airway injury.

Postoperative Care

Patients are taken to the intensive care unit postoperatively and typically remain there for the first postoperative day before transferring to the surgical floor. The typical hospital stay is 7 days in patients with an uncomplicated postoperative course. The nasogastric tube may be removed on day 2 and “trickle” (20 to 30 mL/hr) jejunostomy tube feeds are started. A contrast esophagram is obtained on day 3 to 4 if the patient has adequate pulmonary toilet and a good cough. If there is no evidence of leak, oral intake is initiated in the form of 1 to 2 oz of clear liquids per hour. This is advanced over 2 days to full liquids, no more than 3 to 4 oz/hr along with cycled tube feeds. The chest tube is removed when output low (<150 cc/d) and the clinical course negative for leak. The Jackson–Pratt drain is pulled back 3 to 5 cm on postoperative day 5 and resecured. The drain is removed at the first postoperative clinic visit in 2 weeks’ time.

Figure 43-20. Creation of the esophago-gastric anastomosis. The anvil is secured in the proximal esophagus with two purse-string sutures. The EEA stapler is introduced into the conduit via a gastrotomy and is docked with the anvil keeping the conduit aligned with the lesser curve staple line facing the camera.

Figure 43-21. The gastrotomy is closed with an Endo GIA stapler and this part of the stomach is sent as final gastric margin. Care is taken not to encroach this staple line too close to the circular EEA staple line. A JP drain is left in the esophageal bed posterior to the anastomosis.

PALLIATIVE OPTIONS IN ADVANCED ESOPHAGEAL CANCER

9 In the event that patients have unresectable disease, metastatic disease, or are medically unfit for surgery, numerous palliative therapies are available. The goal of these therapies is to maintain comfort by restoring as much swallowing function as possible and support nutrition.

Figure 43-22. Completed reconstruction.

Nutrition support and hydration can be provided through alternative enteral access. PEG or surgical jejunostomy tube should be placed whenever possible under endoscopic guidance. Open gastrostomy or jejunostomy tubes are an alternative in patients with bulky obstructive lesions who cannot receive a PEG.

Chemotherapy

Chemotherapy can also provide palliation in patients with esophageal cancer. Many regimens are available that have been extensively studied. Agents such as fluorouracil and taxanes may be used either alone or in combination with platin-based agents to provide symptomatic relief. Palliative chemotherapy typically requires time to effectively reduce dysphagia. Special attention is needed while implementing these chemotherapeutic agents in usually debilitated, malnourished patients.

Radiation

Radiotherapy can be used for palliative reasons in patients with dysphagia. The typical dosage used is 4,000 to 5,000 cGy delivered over 4 weeks. The goal for this treatment is to allow patients with

advanced disease and severe obstructive symptoms to handle secretions and swallow liquids such as dietary supplements. Like with palliative chemotherapy, radiotherapy does not offer immediate relief and will require time in order to reach maximal palliative effect. Patients with life expectancies greater than 3 months can be offered a combination of chemotherapy and radiation to achieve palliation. Side effects of radiation therapy include skin irritation and erythema. Patients may also experience esophagitis with painful swallow, stricture formation, radiation pneumonitis, and fistulization to the airway.

Stenting

Stenting technology has advanced significantly since its initial introduction in the 1970s as a palliative option for inoperable malignant esophageal strictures.²³ Currently, many stents are available on the market including self-expanding coated and uncoated nitinol types. Patients have the option of either inserting them endoscopically or radiologically. Stenting can be done in conjunction with other palliative treatment options including balloon dilation, neodymium; yttrium-aluminum-garnet (Nd:YAG) laser fulguration, and photodynamic therapy (PDT), which we will discuss next.

Neodymium:Yttrium-Aluminum-Garnet Laser Fulguration

In patients with unresectable obstructive tumors, endoscopic Nd:YAG laser fulguration is a surgical option that can provide temporary relief of esophageal obstruction. First, an esophagoscope is used to identify the lesion. The YAG laser energy is delivered through a flexible quartz fiber that is passed through the working channel of the scope. Multiple YAG laser sessions will be required to debulk the lumen of the esophagus to the point where patients may function relatively normally. As with many palliative treatments, laser fulguration is often performed in conjuncture with endoluminal stenting and radiation therapy to achieve better functional success. It can be particularly useful in patients who have undergone prior stenting and are experiencing an ingrowth of tumor through the stent. Tumor ingrowth is less of a problem with many of the current stents because we prefer to use the fully covered stents.

Photodynamic Therapy

Another form of palliative therapy is intraluminal PDT. It is a nonthermal ablative technique that requires the systemic administration of a photosensitizing substance such as hematoporphyrin. Over the course of 48 hours, this photosensitizing substance becomes highly concentrated in malignant cells. Patients will then undergo endoscopic evaluation with application of an argon-pump dye-laser introduced endoluminally in the esophagus to deliver light at a wavelength of 630 nm. This endoluminal light source will cause a chain reaction that generates an overwhelming concentration of oxygen radicals, quickly leading to tumor necrosis and patent luminal area. Perforation is of little concern with PDT because the risk of full-thickness necrosis of the esophagus is rare due to the limited depth of penetration of the light. Unfortunately, photosensitizing agents such as hematoporphyrin are frequently retained by the reticuloendothelial system of the skin. This retention will cause patients to be sensitive to infrared wavelength light, including sunlight, radiant heat, fluorescent light, and strong incandescent light. Patients should be informed of these side effects as they may persist for up to 3 months depending on what agent was used as well as the individual. Because of these long-lasting postoperative effects, endoluminal PDT may not be a favored option for patients with shorter life expectancies.

In a recent series of 215 patients who underwent endoluminal PDT for palliation, investigators reported a procedure-related mortality rate of 1.8%. With a median survival of 4.8 months, this series found this technique to be an effective palliative treatment in 85% of patients with obstructive esophageal tumors.⁷⁸ Of note, some of these patients also required stenting for palliation, suggesting that PDT may have a role in a multimodal palliative treatment plan for patients with obstructing esophageal cancers.

SECTION E: STOMACH AND DUODENUM

Chapter 44

Gastric Anatomy and Physiology

Michael W. Mulholland

Key Points

- 1 The stomach is an extremely well-vascularized organ, supplied by a number of major arteries and protected by a large number of extramural and intramural collaterals.
 - 2 Oxyntic glands occupy the fundus and body of the stomach and contain the oxyntic or parietal cells, which are the sites of acid production. Oxyntic glands also contain chief cells, the site of gastric pepsinogen synthesis.
 - 3 The most important stimulant of gastrin release is a meal. Postprandial luminal pH also strongly affects gastrin secretion.
 - 4 The basolateral membrane of the parietal cell contains specific receptors for histamine, gastrin, and acetylcholine, the three major stimulants of acid production.
 - 5 Pepsins are a heterogeneous group of proteolytic enzymes that are secreted by the gastric chief cells.
 - 6 The gastric mucosa is the site of production of intrinsic factor, which is necessary for the absorption of cobalamin from the ileal mucosa. Total gastrectomy is regularly followed by cobalamin malabsorption, as is resection of the proximal stomach or atrophic gastritis that involves the oxyntic mucosa.
-

GROSS ANATOMY

The stomach and duodenum, along with the esophagus, liver, bile ducts, and pancreas, are derived from the embryonic foregut. During the fifth week of gestation, the future stomach is marked as a dilation in the caudal portion of the foregut. Cranial to this dilation, the trachea forms as a bud from the future esophagus. At this time, the primitive stomach is invested with both ventral and dorsal mesenteries. The embryonic ventral mesentery is represented in postnatal life by the falciform ligament and by the gastrohepatic and hepatoduodenal mesenteries that form the lesser omentum. The celiac artery, the major blood supply to the foregut, passes within the dorsal mesentery. The primitive dorsal mesentery ultimately forms three structures: the gastocolic ligament, the gastrosplenic ligament, and the gastrophrenic ligament.

During the sixth and seventh weeks of gestation, the typical morphology of the stomach is established. Accelerated growth of the left gastric wall, relative to the right, establishes the greater and lesser curvatures. This unequal growth also rotates the stomach and causes the left vagal nerve trunk to assume its anterior position, whereas the right vagal trunk is located posteriorly. The growth of structures cephalad to the stomach causes the organ to descend. During the sixth week, the primitive stomach lies between the T10 and T12 vertebral segments. By the eighth week, the stomach is located between the T11 and the L4 segments. In adult life, the stomach is most commonly located between the T10 and the L3 vertebral segments.

The stomach can be divided into anatomic regions based on external landmarks (Fig. 44-1). Although this division is commonly referred to in surgical texts and is useful in discussing gastric resective procedures, it does not necessarily reflect the secretory or motor functions of the mucosal and muscular layers of the stomach. The gastric cardia is the region of the stomach just distal to the gastroesophageal junction. The fundus is the portion of the stomach above and to the left of the gastroesophageal junction. The corpus constitutes the region between the fundus and the antrum. The margin between the corpus and antrum is not distinct externally but can be defined arbitrarily by a line from the incisura angularis on the lesser curvature to a point one-fourth the distance from the pylorus to the esophagus along the greater curvature. The gastric antrum is bounded distally by the pylorus, which can be appreciated by palpation as a thickened ring of smooth muscle.

The stomach is mobile in most people and is fixed at only two points, proximally by the

gastroesophageal junction and distally by the retroperitoneal duodenum. Therefore, the position of the stomach varies and depends on the habitus of the person, the degree of gastric distention, and the position of the other abdominal organs. Anteriorly, the stomach is in contact with the left hemidiaphragm, the left lobe and the anterior segment of the right lobe of the liver, and the anterior parietal surface of the abdominal wall. The posterior surface of the stomach is related to the left diaphragm; the left kidney and left adrenal gland; the neck, tail, and body of the pancreas; the aorta and celiac trunk; and the periaortic nerve plexuses. The greater curvature of the stomach is near the transverse colon and the transverse colonic mesentery. The concavity of the spleen contacts the left lateral portion of the stomach.

1 The stomach is an extremely well-vascularized organ, supplied by a number of major arteries and protected by a large number of extramural and intramural collaterals. Gastric viability can be preserved after ligation of all but one primary artery, an advantage that can be exploited during gastric reconstructive procedures. Also, the rich network of anastomosing vessels means that gastric hemorrhage cannot be controlled by the extramural ligation of gastric arteries. Most gastric blood flow is ordinarily derived from the celiac trunk (Fig. 44-2). The lesser curvature is supplied by the left gastric artery, which is the first major branch of the celiac trunk, and by the right gastric artery, which is derived from the hepatic artery. Branches of the left gastric artery also supply the lowermost portion of the esophagus. The greater curvature is supplied by the short gastric and left gastroepiploic arteries, which are branches of the splenic artery, and by the right gastroepiploic artery, a branch of the gastroduodenal artery. In instances of celiac trunk occlusion, gastric blood flow is usually maintained from the superior mesenteric artery collaterally by way of the pancreaticoduodenal arcade. In general, venous effluent from the stomach parallels the arterial supply. The venous equivalent of the left gastric artery is the coronary vein.

Figure 44-1. Topographic relations of the stomach.

As a first approximation, the lymphatic drainage of the stomach parallels gastric venous return (Fig. 44-3). Lymph from the proximal portion of the stomach along the lesser curvature first drains into superior gastric lymph nodes surrounding the left gastric artery. The distal portion of the lesser curvature drains through suprapyloric nodes. The proximal portion of the greater curvature is supplied by lymphatic vessels that traverse pancreaticosplenic nodes, whereas the antral portion of the greater curvature drains into the subpyloric and omental nodal groups. Secondary drainage from each of these systems eventually traverses nodes at the base of the celiac axis. These discrete anatomic groupings are misleading. The lymphatic drainage of the human stomach, like its blood supply, exhibits extensive intramural ramifications and a number of extramural communications. As a consequence, disease processes that involve the gastric lymphatics often spread intramurally beyond the region of origin and to nodal groups at a distance from the primary lymphatic zone.

The left and right vagal nerves descend parallel to the esophagus within the thorax before forming a periesophageal plexus between the tracheal bifurcation and the diaphragm. From this plexus, two vagal trunks coalesce before passing through the esophageal hiatus of the diaphragm (Fig. 44-4). The left vagal trunk is usually closely applied to the anterior surface of the esophagus, whereas the posterior vagal trunk is often midway between the esophagus and the aorta. The anterior vagus supplies a hepatic

division, which passes to the right in the lesser omentum before innervating the liver and biliary tract. The remainder of the anterior vagal fibers parallels the lesser curvature of the stomach, branching to the anterior gastric wall. The posterior vagus nerve branches into the celiac division, which passes to the celiac plexus, and a posterior gastric division, which innervates the posterior gastric wall.

Figure 44-2. Arterial blood supply of the stomach.

Figure 44-3. Lymphatic drainage of the stomach.

Approximately 90% of the fibers in the vagal trunks are afferent, transmitting information from the gastrointestinal tract to the central nervous system (CNS). Parasympathetic afferent fibers are not responsible for the sensation of gastric pain. Only 10% of vagal nerve fibers are motor or secretory efferents. Parasympathetic efferent fibers contained in the vagus originate in the dorsal nucleus of the medulla. Vagal efferent fibers pass without synapse to contact postsynaptic neurons in the gastric wall in the myenteric and submucous plexuses. Secondary neurons directly innervate gastric smooth muscle or epithelial cells. Acetylcholine is the neurotransmitter of primary vagal efferent neurons.

The gastric sympathetic innervation is derived from spinal segments T5 through T10. Sympathetic fibers leave the corresponding spinal nerve roots by way of gray rami communicantes and enter a series of bilateral prevertebral ganglia (Fig. 44-5). From these ganglia, presynaptic fibers pass through the greater splanchnic nerves to the celiac plexus, where they synapse with secondary sympathetic neurons. Postsynaptic sympathetic nerve fibers enter the stomach in association with blood vessels. Afferent sympathetic fibers pass without synapse from the stomach to dorsal spinal roots. Pain of gastroduodenal origin is sensed through afferent fibers of sympathetic origin.

Figure 44-4. Vagal innervation of the stomach.

Figure 44-5. Derivation of gastric sympathetic innervation.

MICROSCOPIC ANATOMY

The glandular portions of the stomach are lined by a simple columnar epithelium composed of surface mucous cells. The luminal surface, visualized by scanning electron microscopy, appears cobblestoned, interrupted at intervals by gastric pits. Opening into the gastric pits are one or more gastric glands that impart functional significance to the gastric mucosa. The mucosa of the human stomach is composed of three distinct types of gastric glands – cardiac, oxyntic, and antral.

In humans, cardiac glands occupy a narrow zone adjacent to the esophagus and mark a transition from the stratified squamous epithelium of the esophagus to the simple columnar epithelium of the stomach. The surface and gastric pit mucous cells of the cardia are not distinguishable from those in other areas of the stomach. Cardiac glands contain mucous and undifferentiated and endocrine cells but not the parietal or chief cells that are prominent in the adjacent oxyntic mucosa. Cardiac glands are usually branched and connect with relatively short gastric pits. The functional properties of cardiac glands include the secretion of mucus.

2 Oxyntic glands are the most distinctive feature of the human stomach. They occupy the fundus and body of the stomach and contain the oxyntic or parietal cells, which are the sites of acid production. Oxyntic glands also contain chief cells, the site of gastric pepsinogen synthesis. The tubular oxyntic

glands are usually relatively straight but sometimes branch; several glands may empty into a single gastric pit. The glands are divided into three regions: (a) the isthmus, containing surface mucous cells and a few scattered parietal cells; (b) the neck, with a heavy concentration of parietal cells and a few neck mucous cells; and (c) the base of the gland, containing chief cells, undifferentiated cells, a few parietal cells, and some mucous neck cells. Endocrine cells are scattered throughout all three regions of oxyntic glands.

The most distinctive cell of the gastric mucosa is the acid-secreting parietal cell. Parietal cells have an unusual ultrastructural specialization in the form of intracellular canaliculi, a network of clefts extending to the basal cytoplasm and often encircling the nucleus, which is continuous with the gland lumen (Fig. 44-6). The surface area provided by the intracellular secretory canaliculi is large and is further magnified by microvilli lining the canaliculi. In parietal cells that are not stimulated to secrete acid, the secretory canaliculi are collapsed and inconspicuous. On stimulation, a severalfold increase in canalicular surface area occurs, the intracellular clefts become prominent, and the communication with the luminal surface is readily identified. These changes create an intracellular space in communication with the gastric lumen into which hydrogen ions are secreted at high concentration.

The cytoplasm of the parietal cell also contains an abundance of large mitochondria. Mitochondria are estimated to occupy 30% to 40% of the cytoplasmic volume of unstimulated parietal cells, reflecting the extremely high oxidative activity of these cells. The oxygen consumption rate of isolated parietal cells is approximately five times higher than that of gastric mucous cells. The cytoplasm also contains a limited amount of rough endoplasmic reticulum, presumed to be the production site of intrinsic factor, which is also secreted by parietal cells.

Figure 44-6. Resting and stimulated parietal cell, emphasizing morphologic transformation with increase in secretory canalicular membrane surface area that occurs with acid secretion.

Figure 44-7. Contrasting morphology of antral gastrin cell (*left*) with basally oriented secretory granules, and gastric mucous cell (*right*) with apical mucous granules.

In addition to parietal cells, the oxyntic glands contain the gastric chief cells, which synthesize and secrete pepsinogen. Chief cells are most abundant in the basal region of the oxyntic glands. The cells have a morphology typical of protein-secreting exocrine cells and are similar in ultrastructural appearance to pancreatic acinar cells. Rough endoplasmic reticulum is abundant in the cytoplasm and extends between secretory granules. Zymogen granules containing pepsinogen are most concentrated in the apical cytoplasm. Pepsinogen is released by exocytosis from secretory granules at the apical surface of chief cells.

Antral glands occupy the mucosa of the distal stomach and pyloric channel. Antral glands are relatively straight and often empty through deep gastric pits. Although most cells in the antral glands are mucus secreting, gastrin cells are the distinctive feature of this mucosa. Gastrin cells are pyramid shaped, with a narrow area of luminal contact apically and a broad surface overlying the lamina propria basally (Fig. 44-7). Gastrin cells are identified immunocytochemically by the presence of the peptide. Granules ranging from 150 to 400 nm in diameter are the sites of gastrin storage and are most numerous in the basal cytoplasm. Gastrin is released by exocytotic fusion of the secretory granule with the plasma membrane. In contrast to secretion from chief cells, emptying of gastrin-containing granules occurs at the basal membrane rather than at the apical region of the cell. Gastrin thus released diffuses to and enters submucosal capillaries in close apposition to the lamina propria.

GASTRIC PEPTIDES

The stomach contains a number of biologically active peptides in nerves and mucosal endocrine cells, including gastrin, somatostatin, ghrelin, gastrin-releasing peptide, vasoactive intestinal polypeptide (VIP), substance P, glucagon, and calcitonin gene-related peptide. The peptides with the greatest importance to human disease and clinical surgery are gastrin, somatostatin, and ghrelin.

Gastrin

The synthesis, secretion, and action of gastrin have been extensively studied, and many aspects of the biology of gastrin appear to be shared by other gastrointestinal peptide hormones.¹ The gene that encodes for gastrin was isolated using a human DNA library. The human gastrin gene contains three exons; two exons consist of coding sequences. The major active product is encoded by a single exon. In adults, the gastrin gene is expressed primarily in mucosa cells of the gastric antrum, with lower levels of expression in the duodenum, pituitary, and testis. During embryonic development, the gastrin gene is transiently active in pancreatic islets and colonic mucosa.

The human gene encompasses approximately 4,100 base pairs and directs the synthesis of a peptide of 101 amino acids (Fig. 44-8). The resulting peptide, progastrin, contains the sequence of gastrin

within its amino acid sequence. Preprogastrin consists of a signal peptide of 21 amino acids, an intervening peptide of 37 amino acids, the 34-residue region of the gastrin molecule, and a carboxyl-terminal extension of nine amino acids. Gastrin is derived from its preprohormone by the sequential enzymatic cleavage of the signal peptide, the intervening peptide, and the carboxyl-terminal extension.

The signal peptide region of preprogastrin consists of a series of hydrophobic amino acids that direct the nascent peptide into the endoplasmic reticulum as it is translated from messenger RNA. After directing the preprogastrin molecule into the rough endoplasmic reticulum, the signal peptide is removed. The remaining peptide is termed *progastrin*. Progastrin is further processed as it traverses the endoplasmic reticulum to mature secretory vesicles. Enzymatic cleavage at a pair of basic amino acid residues proximal to the gastrin 34 (G_{34}) sequence removes the intervening peptide. A similar cleavage removes a six-amino-acid fragment at the carboxyl-terminal end. The peptide that remains has a Gly-Arg-Arg sequence at the carboxyl terminus. Carboxypeptidase cleaves the Arg residues, and the peptide that results is termed *glycine-extended gastrin*. G_{34} is formed by cleavage of the Gly-Arg-Arg sequence and amidation of the carboxyl-terminal phenylalanine. Gastrin, like most gastrointestinal peptide hormones, requires terminal amidation for biologic activity. Gastrin 17 (G_{17}), the most abundant form of gastrin in the human antrum, is formed by further processing that removes the first 17 amino acids at the amino terminus of G_{34} . G_{34} is the predominate molecular form of gastrin in the duodenum.

Figure 44-8. Sequential processing of preprogastrin molecule.

3 The most important stimulant of gastrin release is a meal. Small peptide fragments and amino acids that result from intragastric proteolysis are the most important food components that stimulate gastrin release. The most potent gastrin-releasing activities are demonstrated by the amino acids tryptophan and phenylalanine. Ingested fat and glucose do not cause gastrin release. Gastric distention by a meal activates cholinergic neurons and stimulates gastrin release. As the meal empties and distention diminishes, VIP-containing neurons are activated, which stimulate somatostatin secretion and thus attenuate gastrin secretion.

Postprandial luminal pH also strongly affects gastrin secretion. Gastrin release is inhibited when acidification of an ingested meal causes the intraluminal pH to fall below 3.0. Conversely, maintaining intragastric pH above 3.0 potentiates gastrin secretion after ingestion of protein or amino acids.² Pernicious anemia and atrophic gastritis, which produce chronic achlorhydria, are associated with fasting hypergastrinemia and an exaggerated gastrin meal response. Release of mucosal somatostatin occurs with gastric acidification and this peptide has been implicated in the inhibition of gastrin release that occurs when luminal pH falls.

The vagus nerve appears to both stimulate and inhibit gastrin release.³ In humans, vagally mediated

stimulation of gastrin release can be demonstrated by sham feeding, insulin-induced hypoglycemia, and administration of the vagal stimulant gamma-aminobutyric acid. In contrast to these stimulatory vagal effects, hypergastrinemia, observed after vagotomy, suggests that inhibitory vagal effects on gastrin release may also exist. Cholinergic neurons stimulate gastrin secretion directly by actions on gastrin cells. By decreasing somatostatin secretion, cholinergic neurons also indirectly stimulate gastrin release. Evidence suggests that vagal stimulation of gastrin release is mediated by bombesin or its mammalian equivalent, gastrin-releasing peptide, acting as a neurotransmitter in the gastric wall. Adrenergic stimulation has also been noted to increase gastrin release.

Chronic gastric infection with *Helicobacter pylori* causes increased acid secretion by altering gastrin release.^{4,5} *H. pylori* has been observed to upregulate proinflammatory cytokines, including interleukin (IL)-6, IL-8, and tumor necrosis factor- α (TNF- α). Several inflammatory mediators have been demonstrated to stimulate gastrin release from isolated gastrin cells. The putative gastrin secretagogues include IL-1, IL-8, TNF- α , interferon-gamma, and leukotrienes C4 and D4. The same factors that affect gastrin release also influence gastrin mRNA expression. Food ingestion increases gastrin mRNA abundance, whereas fasting and somatostatin decrease gastrin mRNA production. Chronic achlorhydria, as seen in pernicious anemia, increases gastrin mRNA production.

In addition to stimulating acid secretion from gastric parietal cells (detailed later in this chapter), gastrin has important physiologic actions in the control of gastrointestinal mucosal growth. The acid-secreting oxyntic mucosa is particularly sensitive to the trophic actions of gastrin, but the mucous membranes of the duodenum, colon, and pancreatic parenchyma are also affected. Stimulation of mucosal growth by gastrin is enhanced by the presence of solid food in the diet. The 17- and 34-amino-acid forms of gastrin are equipotent in stimulating mucosal growth. Prolonged stimulation by high levels of gastrin, as seen in the Zollinger–Ellison syndrome, is associated with hypertrophy of the gastric mucosa. Smaller increases in circulating gastrin, such as those that follow vagotomy, do not cause mucosal hypertrophy.

Figure 44-9. Derivation of somatostatin 14 from preprosomatostatin precursor.

Somatostatin

Somatostatin, like gastrin, is very significant in gastric physiology. Somatostatin was first isolated from hypothalamic tissues and was named for its ability to inhibit the release of growth hormone. The peptide was subsequently localized in neurons in central and peripheral nervous systems, and in endocrine cells in the pancreas, stomach, and intestine.⁶ The wide tissue distribution of somatostatin suggested important regulatory functions, a concept validated by many investigations.

The human somatostatin gene is located on chromosome 3 and encodes for a precursor of 116 amino acids (Fig. 44-9). The somatostatin molecule is contained in the carboxyl-terminal sequence of this preprohormone. The first 24 amino acids of the amino terminus of preprosomatostatin constitute a signal peptide; cleavage of this signal peptide leaves prosomatostatin. Enzymatic cleavage of an additional 64-amino-acid segment from prosomatostatin forms somatostatin 28. Further processing of somatostatin 28 to somatostatin 14 is tissue-specifically regulated. In the stomach, most somatostatin exists as the shorter peptide.

Gastric somatostatin release responds to luminal, hormonal, and neural signals. Luminal acidification is associated with increased somatostatin release, whereas somatostatin release decreases when luminal pH is increased. A number of peptides have been demonstrated experimentally to release somatostatin from the stomach, including gastrin, cholecystikinin, and secretin. β -Adrenergic agonists have also been

shown to release somatostatin. In contrast, electrical stimulation of vagal nerves inhibits somatostatin release, as does the cholinergic agonist methacholine.

The most important gastric function of somatostatin appears to be regulation of acid secretion and gastrin release. Circulating somatostatin appears to be important in modulating gastric acid secretion; locally released somatostatin functions to regulate gastrin release. In each instance, somatostatin serves an inhibitory function, decreasing acid secretion and diminishing the release of gastrin. In animals, antral or duodenal acidification has been associated with an increase in circulating somatostatin. Increases in circulating somatostatin are followed, in turn, by decreased gastric acid secretion. Infusion of exogenous somatostatin in doses that produce somatostatin levels similar to those observed postprandially has also been shown to inhibit acid secretion. In humans, concentrations of somatostatin capable of inhibiting acid secretion can do so without altering serum gastrin levels, indicating a direct action on the acid-secreting fundic mucosa.

Somatostatin is believed to influence gastrin secretion through a locally active intramucosal mechanism. Local actions of somatostatin are supported by ultrastructural studies of antral somatostatin cells, which demonstrate long cytoplasmic processes that make intimate cell-to-cell contact with antral gastrin cells. The presence of somatostatin at these sites of cellular contact implies that somatostatin cells influence the function of gastrin cells through local release of the peptide. Somatostatin can also reach neighboring gastrin cells through diffusion or local blood flow. A number of experiments have suggested that release of somatostatin and gastrin is functionally, although reciprocally, linked. For example, in anesthetized animals, an increase in gastric pH or ingestion of a meal is associated with increases in gastrin and decreases in somatostatin in antral venous blood. Cholinergic agents stimulate gastrin release while inhibiting somatostatin release. Prostaglandin E₂, in contrast, inhibits gastrin release and stimulates somatostatin secretion. These and similar observations suggest that increases in somatostatin release are often associated with decreased gastrin secretion. A family of five somatostatin receptors has been cloned. Inhibition of gastrin-stimulated gastric acid secretion is mediated by somatostatin receptor subtype 2.⁷

GASTRIC ACID SECRETION

Cellular Events

4 An appreciation of the mechanisms that control gastric acid formation is essential to a discussion of gastric disease. An understanding of the cellular basis of acid secretion by the gastric parietal cell also provides a foundation for discussing the pharmacologic treatment of acid-peptic diseases. The basolateral membrane of the parietal cell contains specific receptors for histamine, gastrin, and acetylcholine, the three major stimulants of acid production.⁸ Each stimulant reaches the parietal cell by a different route. Histamine is released from mastlike cells within the lamina propria and diffuses to the mucosa, acetylcholine is released in close proximity to the parietal cells from cholinergic nerve terminals, and gastrin is delivered by the systemic circulation to the fundic mucosa from its source in the antrum and proximal duodenum (Fig. 44-10), activating protein kinase A, which in turn catalyzes protein phosphorylation. The target protein molecules for this phosphorylation, in turn, stimulate acid production.

Figure 44-10. Interactions of cell types that affect parietal cell acid secretion.

Acetylcholine and related cholinergic agonists activate parietal cells after binding to muscarinic receptors. The stimulatory effects of acetylcholine and its congeners can be abolished by atropine. The action of acetylcholine is mediated by muscarinic receptor subtype 3 (M_3). Studies suggest that cholinergic stimulation of parietal cell function is coupled to enhanced mobilization of intracellular calcium. The resultant transient increases in intracellular calcium activate mechanisms that stimulate acid secretion (Fig. 44-11). Evidence also indicates that occupation of acetylcholine receptors increases turnover of specific membrane phospholipids termed *phosphatidylinositides*. Acetylcholine–receptor binding is followed by activation of membrane-associated phospholipase C. Phospholipase C acts on phosphatidylinositol-4,5-bisphosphate (PIP_2) within the plasma membrane to liberate water-soluble inositol triphosphate (IP_3) and diacylglycerol. A major action of IP_3 is to increase intracellular calcium, mainly from intracellular stores in the endoplasmic reticulum. The resulting increased cytosolic calcium interacts with calmodulin or other calcium-binding proteins. Calmodulin kinase type II is involved in parietal cell activation by acetylcholine. Intracellular calcium in this form is postulated to modulate parietal cell function through protein phosphorylation or enzyme activation. Diacylglycerol, the second product released by hydrolysis of PIP_2 , activates a class of protein kinases that are phospholipid dependent and Ca^{2+} activated, protein kinase C. Protein kinase C in turn acts to phosphorylate a set of proteins that are distinct from those affected by the calmodulin-dependent system. The ultimate result of this protein phosphorylation is parietal cell activation and hydrogen ion secretion.

Parietal cells can also be activated by occupation of specific gastrin receptors. As with cholinergic stimulation, gastrin exposure increases membrane PIP_2 turnover (Fig. 44-11). Like acetylcholine, the actions of gastrin depend highly on increases in intracellular calcium and activation of protein kinase C.

Although histamine, acetylcholine, and gastrin occupy separate receptors on the parietal cell and activate differing second-messenger systems, each secretagogue ultimately acts by means of a specialized ion transport system called the *parietal cell proton pump*. This membrane-bound protein is located in the secretory canaliculus of the parietal cell; the peptide has not been identified in other gastric cells or in significant amounts in other organs. The proton pump is an H^+-K^+ -adenosine triphosphatase (ATPase) that electroneutrally exchanges cytosolic H^+ for luminal K^+ . Hydrogen ions are concentrated 2.5-million-fold within the secretory canaliculus, and the hydrolysis of ATP is the energy source for transport against the steep electrochemical gradient generated. For each H^+ ion transported to the luminal surface of the canicular membrane, one K^+ ion is transported to the cytosolic surface (Fig. 44-12). This cotransport requires that K^+ be continuously supplied to the luminal surface of the secretory membrane. This requirement is satisfied by conductance of K^+ across the canicular membrane from intracellular stores. Chloride ions also enter the secretory canaliculus by diffusion.

Activation of the H^+-K^+ -ATPase significantly increases intracellular OH^- generation, with potential cellular toxicity. Carbonic anhydrase, which is associated with the canicular membrane, converts OH^- to HCO_3^- . The HCO_3^- produced is disposed of by exchange for Cl^- at the basolateral membrane.

Intracellular Cl^- thus acquired supplies the necessary Cl^- on a one-to-one basis for each H^+ secreted. The transcellular exchange of H^+ for HCO_3^- ensures that the voluminous secretion of hydrochloride at the luminal surface of the gastric mucosa is matched by an equivalent delivery of base to submucosal capillaries. Parietal cell ionic transport pathways are shown in [Figure 44-13](#).

Figure 44-11. Cellular mechanisms controlling parietal cell acid secretion. ADP, adenosine diphosphate; ATP, adenosine triphosphate; cAMP, cyclic adenosine monophosphate; PI, phosphatidylinositol; PIP, phosphatidylinositol-4,5-phosphate; PIP₂, phosphatidylinositol-4,5-bisphosphate; RER, rough endoplasmic reticulum.

The function of the proton pump is highly regulated. In the unstimulated state, the enzyme is sequestered in cytoplasmic structures termed *tubulovesicles* that are not connected to the gastric lumen. Tubulovesicle membranes in this state have a low permeability to KCl. Stimulation of acid secretion causes tubulovesicles to fuse with apical secretory membranes and increases membrane permeability to KCl. In this way, the fusion of tubulovesicle membrane exposes the H⁺-K⁺ pump to the gastric lumen and simultaneously provides the K⁺ substrate necessary for acid secretion.

Parietal cells also contain membrane receptors that inhibit acid secretion. Specific receptors for somatostatin have been identified using isolated gastric cells. Activation of isolated parietal cells by histamine, pentagastrin, or the cholinergic agonist carbachol can be blocked by somatostatin 28. In the case of histamine activation, the inhibitory effects appear to be mediated by the ability of somatostatin to block the production of cyclic adenosine monophosphate (cAMP). Somatostatin appears to inhibit the actions of these agonists at a point distal to second-messenger generation. Gastric parietal cells also contain receptors for prostaglandins, notably prostaglandin E₂ and its derivatives. Prostaglandin E₂ is a potent inhibitor of histamine-stimulated parietal cell activation, probably by a mechanism that inhibits formation of cAMP. Prostaglandin inhibition is specific for histamine; the actions of gastrin or carbachol are not affected. Epidermal growth factor and transforming growth factor- α also inhibit histamine-stimulated acid secretion through effects on cAMP production.

Figure 44-12. Gastric $\text{H}^+\text{-K}^+$ -adenosine triphosphatase (ATPase). ADP, adenosine diphosphate; ATP, adenosine triphosphate; P_i , phosphate ion.

Figure 44-13. Ionic fluxes associated with acid secretion by the parietal cell.

These considerations of the cellular basis of acid production demonstrate how parietal cell function can be altered pharmacologically. Gastric acid production can be blocked by receptor antagonists for each of the three primary stimulants – gastrin, acetylcholine, and histamine. Direct inhibition of acid production can be effected by derivatives of somatostatin or prostaglandin E_2 . All forms of stimulated acid production can be blocked by agents that act as inhibitors of the parietal cell proton pump. Agents that act at each of these points have been developed, and their appropriate clinical applications are discussed in subsequent chapters.

Regulation of Acid Secretion

Given the multiple receptors on parietal cells, it is not surprising that a great deal of secretagogue interdependence, both stimulatory and inhibitory, exists in humans. Parietal cell activation, and the resultant acid secretion, is greater in response to a combination of agonists than it is in response to the total effect of agents used singly. This increase in responsiveness is defined as *potentiation*. Potentiating interactions are most apparent when agents are used that act by way of different second-messenger systems. Thus, histamine strongly potentiates the acid-secretory response to pentagastrin or to carbachol in humans. Conversely, blockade of receptors to one stimulant also decreases responsiveness to the other agonists. For example, blocking histamine receptors with agents such as cimetidine decreases responsiveness to pentagastrin, even though gastrin receptors are not directly affected. These inhibitory interactions are exploited therapeutically in the treatment of acid-peptic diseases.

Humans normally secrete 2 to 5 mEq/hr of hydrochloride in the fasting state, constituting basal acid secretion. Both vagal tone and ambient histamine secretion are presumed to be important in determining the rate of basal acid secretion. In humans, truncal vagotomy decreases basal secretion by approximately 85%. Similarly, H_2 -receptor antagonists also inhibit basal acid secretion by approximately 80%. Gastrin does not have an important role in determining basal acid secretion in normal people.

Stimulated acid secretion begins with the thought, sight, or smell of food (Fig. 44-14). This cephalic phase of gastric acid secretion is mediated by the vagus nerve. Vagal discharge directs a cholinergic mechanism, and the cephalic phase of acid secretion can be inhibited by administering atropine. Vagal discharge secondary to cephalic stimulation also inhibits the release of somatostatin. Diminished secretion of somatostatin further augments stimulatory vagal effects, presumably by eliminating tonic inhibition of acid secretion exerted by somatostatin. The cephalic component of acid secretion can be measured in normal people by sham feeding and is approximately 10 mEq/hr. The cephalic phase approximates 40% of the maximal acid-secretory response to gastrin infusion.

The gastric phase of acid secretion begins when food enters the stomach. The presence of partially hydrolyzed food constituents, gastric distention, and the buffering capacity of food all stimulate acid secretion. Gastrin is the most important mediator of the gastric phase of acid secretion. In normal humans, acid-secretory rates after a mixed meal average 15 to 25 mEq/hr, approximately 75% of the maximal response achieved with infusion of exogenous gastrin or histamine. The meal response is less than the maximal response to exogenous stimulants because food also causes the release of somatostatin

and initiates other inhibitory responses. In humans, 90% of meal-stimulated acid secretion is mediated by gastrin release.⁹

The inhibitory regulation of gastric acid secretion is accomplished by CNS, gastric, and intestinal mechanisms. Stimulated acid secretion can be inhibited experimentally by administering various neuropeptides into the lateral cerebral ventricles, including gastrin-releasing peptide (bombesin), corticotropin-releasing factor, and calcitonin gene-related peptide. Although the relevance of these observations to human physiology remains to be determined, it is likely that CNS inhibition of acid secretion exists in humans. In this regard, the vagus nerve has both a stimulatory and an inhibitory role in acid secretion and gastrin release. Vagotomy causes fasting and postprandial hypergastrinemia, indicating that an inhibitory regulation of gastrin release normally exists. Hypergastrinemia is sustained long term after vagotomy by hyperplasia of antral gastrin cells. The vagal fibers to the oxyntic region of the stomach appear to mediate this inhibitory effect.

Figure 44-14. Regulation of acid secretion in vivo. TRH, thyroid-releasing hormone.

In humans, the most important and clearly established gastric inhibitory influence is the suppression of gastrin release when the antral mucosa is exposed to acid. When luminal pH falls to 2.0, gastrin release stops. Antral acidification also suppresses the gastrin response to an ingested meal. Somatostatin acting locally in the gastric mucosa as a paracrine agent may mediate this important inhibitory response. Release of gastric somatostatin is reciprocally linked to that of gastrin; acidification of the antrum causes increases in somatostatin release and decreases in gastrin secretion. Antral distention also inhibits stimulated acid secretion.

The entry of digestive products into the intestine begins intestinal-phase inhibition of gastric acid secretion. Acidification of the duodenal bulb inhibits acid secretion, and although exogenous secretin also can inhibit acid secretion, this effect appears to be independent of the release of secretin from the duodenal mucosa. Hyperosmolar solutions and those containing fat also potently inhibit acid secretion. Several peptides, including secretin, somatostatin, peptide YY, gastric inhibitory peptide, and neurotensin, have been proposed as mediators of the intestinal phase effects.

PEPSIN

5 Pepsins are a heterogeneous group of proteolytic enzymes that are secreted by the gastric chief cells. Pepsin is derived under acidic conditions from pepsinogen by the autocatalytic loss of a variable amino-terminal sequence of the parent compound. This conversion occurs slowly at pH values of 5.0 to 6.0 and occurs rapidly when luminal pH approximates 2.0. Pepsin catalyzes the hydrolysis of a wide variety of peptide bonds that contain acidic residues, with a pH optimum for hydrolysis between 1.5 and 2.5. Once activated, pepsin is sensitive to ambient pH values; it is irreversibly denatured at pH 7.0 or greater.

The most important stimulus for pepsinogen secretion is cholinergic stimulation. Acetylcholine and its

derivatives stimulate pepsinogen secretion by a mechanism that can be antagonized by atropine, indicating a muscarinic receptor. The receptor is an M_1 type. Endogenous cholinergic stimulation through the vagal nerve results in the formation of a gastric secretion that is rich in pepsin. Although both exogenous histamine and gastrin can stimulate pepsin secretion, their actions appear to be indirectly due to the concomitant secretion of gastric acid rather than to direct stimulation of chief cells. Chief cells have also been shown to possess cholecystokinin receptors, and cholecystokinin-like peptides appear to have a direct stimulatory action on chief cells. The oxyntic mucosa contains somatostatin cells near chief cells. Pepsinogen secretion in response to a variety of stimuli has been demonstrated to be inhibited by somatostatin.

The major physiologic function of pepsin is to initiate protein digestion. Pepsin is highly active against collagen and may be important in the digestion of animal protein. Intragastric protein hydrolysis by pepsin is incomplete, and relatively large peptides enter the intestine, although amino acids and small peptide fragments are released. These products of partial hydrolysis are important signals for gastrin and cholecystokinin release, which in turn regulate digestive processes. In this way, pepsin also contributes to the overall coordination of the digestive process.

INTRINSIC FACTOR

6 The gastric mucosa is the site of production of intrinsic factor, which is necessary for the absorption of cobalamin from the ileal mucosa. Total gastrectomy is regularly followed by cobalamin malabsorption, as is resection of the proximal stomach or atrophic gastritis that involves the oxyntic mucosa.

Autoradiographic and immunocytochemical techniques have confirmed the parietal cell as the site of intrinsic factor synthesis and storage in humans. Intrinsic factor secretion, like acid secretion, is stimulated by histamine, acetylcholine, and gastrin. Unlike acid production, intrinsic factor secretion peaks rapidly after stimulation and then returns to baseline. The amount of intrinsic factor secreted usually greatly exceeds the amount needed to bind and absorb available dietary cobalamin.

GASTRIC BICARBONATE PRODUCTION

It is generally agreed that the gastric mucosa secretes HCO_3^- in addition to acid. The cells responsible for HCO_3^- production are presumed to be the surface mucous cells facing the gastric lumen, and HCO_3^- transport has been postulated to protect against damage from luminal acid. In theory, H^+ ions diffusing from luminal bulk fluids toward the gastric mucosa could be neutralized by secreted HCO_3^- near the surface (Fig. 44-15). In this way, nearly neutral pH can be maintained at the mucosal surface, even if the total amount of hydrochloride secreted greatly exceeds gastric HCO_3^- production. The occurrence of pH gradients at the surface of the gastric mucosa have been demonstrated in humans using microelectrodes. Drugs or chemicals that inhibit bicarbonate secretion result in acidification of the mucosal surface.

The degree of luminal acidity, reflected by pH, required to stimulate bicarbonate secretion is greater in the stomach than in the duodenum. Direct exposure of the gastric mucosa to pH levels of 2.0 or more increases bicarbonate secretion. In the duodenum, exposure of the mucosa to pH 5.0 doubles bicarbonate secretion, whereas exposure to pH 2.0 increases alkaline secretion 10-fold.

Cholinergic agonists, vagal nerve stimulation, and sham feeding have all been shown to increase gastric HCO_3^- production. The effects of cholinergic stimulation can be blocked by atropine. In the human stomach, exposure to luminal perfusates at pH 2.0 has been associated with increased release of prostaglandin E_2 . Prostaglandin E_2 and its synthetic derivatives are also potent stimulants of gastric bicarbonate secretion. Because mucosal bicarbonate production can be decreased in experimental models by indomethacin, endogenous prostaglandins are thought to be important in the mucosal alkaline response.

GASTRIC BLOOD FLOW

Because the gastric mucosa is metabolically highly active, control of mucosal blood flow is of great physiologic importance. In addition, studies have implicated perfusion abnormalities in the development of mucosal lesions during periods of stress. Mucosal blood flow is regulated by neural, hormonal, and

locally active influences.

Postganglionic sympathetic nerve fibers reach the stomach in association with its blood supply and richly innervate small mucosal arteries. Mucosal capillaries do not receive adrenergic innervation. Electrical stimulation of sympathetic nerves supplying the stomach is followed by decreased total gastric blood flow, decreased flow in celiac and gastroepiploic vessels, and diminished blood flow to the mucosa. Studies in animals demonstrate that vasoconstriction of the gastric vascular bed is mediated by α -adrenergic receptors and that vasodilation is mediated by β -adrenergic receptors.

Figure 44-15. Schematic representation of mucosal bicarbonate secretion showing neutralization of luminal hydrogen ions immediately above the mucosal surface.

Stimulation of the vagus nerve is followed by a prompt increase in blood flow, suggesting a dilatory effect of parasympathetic nerves. The effects of vagal stimulation on mucosal blood flow are complicated by accompanying increases in acid secretion. Almost all stimuli that increase acid production also increase blood flow secondarily.

A number of gastrointestinal peptide hormones affect gastric blood flow, most because of their ability to increase or decrease acid secretion. Thus, gastrin, because it is a potent stimulant of acid secretion, also increases mucosal blood flow. Cholecystokinin appears to have direct vasodilatory effects on the gastric vasculature. Vasopressin has been well demonstrated to have direct vasoconstrictor activity.

Nitric oxide modulates basal gastric vascular tone and controls gastric vasodilation and hyperemia. Nitric oxide mediates the hyperemic response that accompanies increases in acid secretion, although the molecule has no direct stimulatory role in acid production.

Prostaglandins are important mucosally produced compounds that have clear effects on the gastric vasculature. Prostaglandins of the E class have been shown in animals and humans to increase gastric blood flow at doses that decrease acid secretion. Indomethacin, in doses sufficient to inhibit prostaglandin formation, decreases the diameter of submucosal blood vessels and reduces basal blood flow. Complete inhibition of cyclooxygenase activity causes an approximate 50% reduction in resting blood flow. These studies suggest that endogenous, locally produced prostaglandins are crucial to maintaining basal gastric blood flow in humans and probably act in concert with endogenous nitric oxide.

GASTRIC MOTILITY

Gastric Smooth Muscle

Consideration of gastric motility requires that the stomach be viewed in functional terms as two different regions, the proximal one-third and the distal two-thirds. These areas are distinct in terms of smooth muscle anatomy, electrical activity, and contractile function. The regions do not correspond to the traditional anatomic divisions of fundus, corpus, and antrum.

In the proximal stomach, three layers of gastric smooth muscle can be distinguished: an outer longitudinal layer, a middle circular layer, and an inner oblique layer. In the distal two-thirds of the stomach, the longitudinal layer is most clearly defined, and the inner oblique layer is usually not distinct. The gastric smooth muscle ends at the pylorus.

The smooth muscle of the proximal stomach is electrically stable, whereas the smooth muscle of the distal stomach demonstrates spontaneous, repeated electrical discharges. Gastric smooth muscle exhibits myoelectric activity that is based on a highly regular pattern called the *slow wave*.¹⁰ In the stomach,

slow waves occur with a frequency of three cycles per minute. Slow waves do not, by themselves, lead to gastric contractions, but they do set the maximum rate of contractions at three per minute. Gastric contractions occur when action potentials are phase locked with the crest of the slow wave.

Extracellular electrical recording from the serosal surface of the stomach also demonstrates the intrinsic electrical activity of the distal stomach in the form of pacemaker potentials. Pacemaker potentials reflect partial depolarization of the gastric smooth muscle cell and are recorded during relatively long periods (2 or 3 seconds). Pacemakers originate along the greater curvature at a point in the proximal third of the stomach. Pacemaker potentials, discharging at a rate of three times per minute in humans, drive cells located distally. Spread of the pacemaker potentials is faster along the greater curvature, so that a ring of electrical activity reaches the pylorus simultaneously along both curvatures. The pacemaker potentials do not result in smooth muscle contraction unless an additional depolarization is superimposed in the form of an action potential. When action potentials occur, a ring of smooth muscle contraction moves peristaltically along the distal stomach toward the pylorus.

Duodenal slow-wave frequency and maximum rate of phasic contractions are higher than those observed in the stomach. The duodenal rate is approximately 12 cycles per minute; the contraction rate declines progressively to nine cycles per minute in the distal ileum.

The smooth muscle activity of the proximal stomach is fundamentally different from that of the distal stomach. There are no pacemakers or action potentials in the proximal stomach. As a result, peristalsis does not occur. Proximal gastric contraction is tonic and prolonged, and increases in luminal pressure are often sustained for several minutes.

Coordination of Contraction

Important vagally mediated reflexes influence intragastric pressure, presumably by affecting contractile activity of smooth muscle in the proximal stomach. The most important reflex is termed *receptive relaxation* and occurs with ingestion of a meal. Increasing gastric volumes are accommodated with little increase in intragastric pressure by relaxation of the proximal stomach. This receptive relaxation allows the proximal stomach to act as a storage site for ingested food in the immediate postprandial period. Afferent impulses, presumed to originate from stretch receptors in the gastric wall, are carried along vagal fibers; efferent vagal discharges are inhibitory. Receptive gastric accommodation is lost after either truncal or proximal gastric vagotomy. After the meal has been ingested, proximal contractile activity increases; alterations in proximal gastric tone cause the compressive movement of gastric content from the fundus to the antrum.

Food that enters the antrum from the proximal stomach is propelled peristaltically toward the pylorus. A number of observations indicate that the pylorus closes 2 or 3 seconds before the arrival of the antral contraction ring. This coordinate closing of the pylorus allows a small bolus of liquid and suspended food particles to pass while retropulsing the main mass of gastric contents back into the proximal antrum. The churning action that results, mixes ingested food particles, gastric acid, and pepsin, and contributes to the grinding function of the stomach. Solid food particles do not ordinarily pass the pylorus unless they are no larger than 1 mm.

A consistent finding in humans ingesting a mixed solid-liquid meal is that liquids empty more quickly than solids. Characteristically, solid food empties only after a lag period, whereas liquid emptying begins almost immediately. A traditional interpretation of these human observations has been that the proximal stomach is the dominant force in determining how quickly a liquid meal empties by the gastroduodenal pressure gradient generated by proximal gastric contractions. The actions of the proximal stomach in liquid emptying are also regulated by the sieving actions of the antropyloric segment and are modified by the nutrient composition of the ingested meal. The distal gastric segment has been postulated to control solid emptying through its grinding and peristaltic actions. This traditional concept of the two-component stomach is useful in considering observations in patients who have undergone gastric operative procedures. Patients who have undergone proximal gastric vagotomy exhibit accelerated emptying of liquids but have normal solid emptying. Because of loss of receptive relaxation, the denervation of the proximal stomach is presumed to increase intragastric pressure and accelerate liquid emptying while leaving the distal gastric segment unaffected. Conversely, vagal denervation of the antrum interrupts gastric emptying of solids to a greater degree than liquids. Although this model of gastric emptying oversimplifies the many mechanisms (gastric, pyloric, and intestinal) that work in concert to control gastric emptying, it provides a useful framework for considering the effects of gastric surgical procedures.

Chapter 45

Gastroduodenal Ulceration

Michael W. Mulholland

Key Points

- 1 Mucosal infection with *Helicobacter pylori* is the factor that contributes to ulcer pathogenesis in most patients.
 - 2 *H. pylori* virulence factors include vacuolating cytotoxin A (VacA) and cytotoxin-associated gene A (CagA).
 - 3 As a group, patients with duodenal ulcers have an increased capacity for gastric acid secretion relative to normal people.
 - 4 Current treatment of peptic ulceration involves a combination of an antisecretory drug, usually a proton pump inhibitor, with antibiotics.
 - 5 Hemorrhage is the leading cause of death associated with peptic ulcer. Patients with recurrent hemorrhage and elderly patients are at greatest risk of death.
 - 6 For perforation, current therapy includes omental patch closure with postoperative anti-*H. pylori* therapy. Minimally invasive approaches are becoming standard practice.
 - 7 Major trauma accompanied by shock, sepsis, respiratory failure, hemorrhage, or multiorgan injury is often accompanied by acute stress gastritis.
-

EPIDEMIOLOGY

Peptic ulceration remains a major public health problem worldwide. Worldwide prevalence of peptic ulcer disease ranges from 0.1% to 4.7% with an overall incidence of 0.2% to 0.3%.¹ With improving public hygiene and effective treatment of *Helicobacter pylori*, most epidemiologic studies are now reporting falling incidence rates. The surgical treatment of peptic ulcer has changed fundamentally. New insights into disease pathogenesis, especially the realization that gastric infection has a role in most cases of peptic ulceration, have been especially exciting. Antibiotics are now front-line antiulcer therapy. A number of powerful antisecretory drugs have been introduced into clinical practice. Medical, endoscopic, and surgical therapies are frequently integrated in the care of individual patients.

PATHOPHYSIOLOGY

1 The pathogenesis of peptic ulceration is complex and multifactorial but increasingly understood. Approximately 75% of peptic ulcer cases are caused by *H. pylori*, with almost all other cases due to use of nonsteroidal anti-inflammatory drugs (NSAIDs).² Both NSAID use and *H. pylori* infection are independent risk factors for development of peptic ulcer disease. The development of peptic ulceration is often depicted as a balance between chronic inflammatory injury, acid-peptic secretion, and mucosal defense, with the equilibrium shifted toward disease. Although acid-peptic secretion is crucial in the development of ulcers, usually a defect in mucosal defense induced by bacterial infection also exists to tip the balance away from health. Mucosal infection with *H. pylori* is the factor that contributes to ulcer pathogenesis in most patients.

Helicobacter pylori

The relation between *H. pylori* infection and ulceration is inferential but overwhelmingly strong; a causal relation between *H. pylori* infection and peptic ulceration has not been tested directly. Because *H. pylori* infection is difficult to eradicate with certainty, and because of the potentially serious consequences of infection, the intentional exposure of humans to the organism to establish such a

relation is not justified.

Many lines of evidence establish *H. pylori* as a factor in the pathogenesis of duodenal ulceration:

- *H. pylori* is the primary cause of chronic active gastritis, characterized by nonerosive inflammation of the gastric mucosa. Antral gastritis is nearly always present histologically in patients with duodenal ulcer, and *H. pylori* can be isolated from gastric mucosa in almost all cases.
- Gastric metaplasia is extremely common in duodenal epithelium surrounding areas of ulceration. *H. pylori* binds only to gastric-type epithelium, regardless of location; metaplastic gastric epithelium can become colonized by *H. pylori* from gastric sources. Gastric metaplasia of the duodenal bulb is a nonspecific response to damage and is the means by which antral gastritis with *H. pylori* is converted to active chronic duodenitis.
- Eradication of *H. pylori* with antimicrobials that have no effect on acid secretion leads to ulcer healing rates superior to those seen with acid-suppressing agents.
- Relapse of duodenal ulcer after antimicrobial therapy is preceded by reinfection of the gastric mucosa by *H. pylori*.

In addition, half of patients evaluated for dyspepsia, but without ulceration, have histologic evidence of mucosal bacterial infection. Furthermore, 20% of healthy volunteers harbor the bacteria; the incidence of bacterial carriage in the healthy, asymptomatic population increases with age. The occurrence of peptic ulcers in only a small proportion of people who carry the organism suggests that other factors must also act to induce ulceration. The ability of *H. pylori* infection to induce alterations in gastric acid secretion is a prerequisite for ulcer development in most patients.

H. pylori is the most common bacterial infection worldwide. *H. pylori* infection is usually *acquired in childhood and lasts lifelong in the absence of specific therapy*. Epidemiologic studies suggest that *H. pylori* infection occurs via person-to-person contact, usually among family members. Transmission is believed to occur during a bout of gastroenteritis; the highest risk is associated with vomiting.

H. pylori is the only human bacterium to persistently infect the stomach. The organism is actually somewhat fragile, being killed by exposure to high levels of oxygen and to the low pH found in the acidic lumen of the stomach. To avoid the bactericidal activity of the stomach, the organism has evolved mechanisms to move within the gastric environment, to adhere to gastric mucosa, and to protect itself from the harmful effects of acid. Over 300 genes of *H. pylori* are regulated by acid.

H. pylori bacteria are spiral shaped with polar flagella. Most bacilli are free-swimming within the mucous layer covering the gastric epithelium. The organisms orient according to a pH gradient, moving away from the lower pH of the lumen toward the epithelium. The majority of organisms remain motile within the mucous layer, but contact promotes adherence to epithelial cells, particularly in the region of intercellular junctions. The products of more than 30 genes are expressed on the outer membrane of the bacterium and function as adhesins to promote attachment to the gastric cells' surface. The best-characterized adhesin binds to the Lewis blood group antigen b. Adhesion triggers the expression of other bacterial genes, including bacterial virulence factors.

2 All strains of *H. pylori* cause persistent infection and all strains induce gastric inflammation. Yet, only 15% of infected individuals develop peptic ulceration and only 1% develop gastric adenocarcinoma. Differential expression of bacterial virulence factors is presumed to account for these observations. Two virulence factors are best characterized: vacuolating cytotoxin A (VacA) and cytotoxin-associated gene A (CagA) (Table 45-1).³

VacA is a pore-forming cytotoxin. VacA is expressed in all strains of *H. pylori* but is polymorphic with marked variation in two regions. The VacA protein is 88 kD. Upon secretion from the bacterium, the protein moves to the host cell membrane, where it forms a ring structure in the shape of a flower.⁴ This ring complex inserts into the membrane of the host cell, creating a pore. VacA pores are permeable to anions and small neutral molecules, including urea. Pore formation may be a mechanism by which the organism obtains nutrients from gastric epithelial cells.

VacA also inserts into endosomal membranes, leading to osmotic swelling. VacA induces gastric cell death through apoptosis. This action is thought to occur via pore formation in mitochondrial membranes. VacA has been reported to interfere with immune T-cell activation and proliferation. This activity may inhibit clearance of the organism by immune mechanisms.

The second major virulence factor in *H. pylori* is termed CagA.^{5,6} The CagA gene is part of a region of DNA that is inserted into the genome of more virulent strains of *H. pylori*, termed a *pathogenicity island*.⁵ The genes in this island that are adjacent to the CagA gene encode proteins, which function as microscopic needles for the transfer of bacterial products into host gastric cells. CagA is transferred to host cells through this injection mechanism.

Table 45-1 *Helicobacter Pylori* Virulence Factors

Vacuolating Cytotoxin A (VacA)
Forms ring structure in the shape of a flower
Inserts into gastric cell membrane, forming pore
Inserts into endosomal membranes, causing cellular swelling
Damages mitochondrial membranes
Causes leakage of ions and small molecules
Cytotoxin-Associated Gene A (CagA)
Contained within pathogenicity island DNA sequence
Injected into host cells
Phosphorylated by cellular oncogenes
Activates growth factor receptor-like signaling
Disturbs normal proliferation, adhesion, cytoskeletal function
Disturbs intercellular junctions, causing disruption of epithelial permeability
Elicits inflammatory response

After CagA protein is transferred to host cells, it becomes phosphorylated on tyrosine residues by host cell kinases. Phosphorylated CagA activates a number of cellular signaling pathways involved in cellular polarity, cytoskeletal protein function, and cellular proliferation and differentiation. As a consequence, infected gastric cells change shape and become more elongated. Apical junctions between cells become disrupted, gaps develop between epithelial cells, and epithelial barrier function is lost. CagA protein also stimulates transcription factors involved in regulation of cellular proliferation. Disturbance of cellular function in favor of apoptosis affects epithelia restitution and may inhibit ulcer healing.

Acid-Secretory Status

3 The formation of duodenal ulcers depends on gastric secretion of acid and pepsin. As a group, patients with duodenal ulcers have an increased capacity for gastric acid secretion relative to normal people (Table 45-2). The maximal acid output of normal men is approximately 20 mEq/h in response to intravenous histamine stimulation, whereas patients with duodenal ulcer secrete an average of approximately 40 mEq/h. Considerable overlap exists between these two groups, and the values for most people with duodenal ulcer fall within the normal range. The increase in acid secretion in some patients with duodenal ulcer has been postulated to be due to an increase in the mass of parietal cells in the acid-secreting gastric mucosa or to an increased sensitivity to circulating gastrin.

Groups of patients with duodenal ulcer demonstrate a prolonged and larger acid-secretory response to a mixed meal than do groups of normal subjects. As with histamine-stimulated acid output, overlap exists between patients with duodenal ulcer and normal subjects. Disturbances in gastric motility can exacerbate meal-stimulated acid-secretory abnormalities.

Patients with duodenal ulcer have accelerated emptying of gastric contents, particularly liquids, after a meal, and duodenal acidification fails to slow emptying appropriately. In such patients, the duodenal mucosa can be exposed to low pH for prolonged periods relative to normal subjects.

ETIOLOGY

Table 45-2 Pathogenesis of Peptic Ulcer

<i>Helicobacter pylori</i> infection
Endocrine Consequences
■ Increased basal serum gastrin
■ Increased gastrin response to a meal
■ Increased responsiveness to gastrin-releasing peptide
■ Production of N ^a -methylhistamine
■ Decreased density of somatostatin cells
■ Decreased mucosal somatostatin content
Gastric Acid Secretion
■ Increased acid = secretory capacity
■ Increased basal secretion
■ Increased pentagastrin-stimulated output
■ Increased meal response
■ Abnormal gastric emptying
Mucosal Defense
■ Decreased duodenal bicarbonate production
■ Decreased gastric mucosal prostaglandin production
■ Increased apoptosis of epithelial cells
■ Disruption of epithelial barrier function
■ Inhibited epithelial restitution

Groups of patients with duodenal ulcer also demonstrate increased basal secretion of acid. Increased

basal secretion can be demonstrated by nocturnal collection of gastric secretions.

Studies indicate that most of these secretory abnormalities are a direct consequence of *H. pylori* infection. Paradoxically, the earliest stages of *H. pylori* infection are accompanied by a marked decrease in gastric acid secretion. Acute antral gastritis is followed by fundal inflammation. Fundal inflammation is associated with mucosal production of a number of cytokines, including interleukin (IL)-1 β , IL-6, IL-8, and tumor necrosis factor- α (TNF- α). IL-1 β is a potent inhibitor of gastric acid secretion. Investigators have postulated that acute reduction in gastric acid secretion facilitates further gastric colonization with *H. pylori*. Acute hypochlorhydria resolves despite persistence of *H. pylori* and is followed by a state of chronically increased acid secretion.

Basal and peak acid outputs are increased in patients with duodenal ulcer infected with *H. pylori* relative to uninfected healthy volunteers. With eradication of *H. pylori* infection, basal acid output returns to normal within 4 weeks, and peak acid output declines to the normal range by 6 months. Peak acid output reflects parietal cell mass; the slow return to normal levels suggests that *H. pylori* infection may stimulate increases in the parietal cell mass.

Abnormalities in acid secretion and parietal cell mass appear to be due to *H. pylori*-induced hypergastrinemia.⁷ *H. pylori*-infected patients have increased basal serum gastrin levels, increased gastrin responses to meal stimulation, and an augmented gastrin response to intravenous gastrin-releasing peptide. Eradication of *H. pylori* infection causes serum gastrin levels to return to baseline. Gastric mucosal inflammatory cells and epithelial cells are activated by *H. pylori* infection to release cytokines such as IL-8, interferon- γ , and TNF- α . These cytokines are stimulants of gastrin release from cultured canine gastrin cells.

H. pylori expresses N α -histamine methyltransferase activity. This enzyme produces N α -methylhistamine, an abnormal analogue of histamine that can act as a gastric acid-secretory stimulant.

The concentration of somatostatin in the antral mucosa and the number of somatostatin-producing cells in the antrum are diminished in *H. pylori*-infected patients. Treatment of *H. pylori* infection is followed by increases in numbers of somatostatin cells and in mucosal somatostatin messenger RNA levels. These observations suggest that alterations in mucosal somatostatin metabolism may also contribute to the hypergastrinemia seen in *H. pylori*-infected patients by removing the inhibitory effects that somatostatin exerts on gastrin release. Somatostatin release is also suppressed by N α -methylhistamine.

Mucosal Defense against Peptic Injury

Gastric surface epithelial cells secrete mucus and bicarbonate, creating a pH gradient within the mucous layer that is nearly neutral at the mucous cell surface, even when the lumen is highly acidic. Failure of normal bicarbonate secretion locally would, in theory, result in exposure of surface epithelial cells to the peptic activity of gastric secretions at low pH. Patients with duodenal ulcers have been demonstrated to have significantly lower basal bicarbonate secretion in the proximal duodenum than normal subjects. In addition, in response to a physiologically relevant amount of hydrochloric acid instilled into the duodenal bulb, stimulated bicarbonate output was approximately 40% of the normal response. Abnormalities in duodenal bicarbonate secretion normalize after elimination of *H. pylori* in infected patients. These results suggest one mechanism by which ulceration could occur, even in patients secreting normal amounts of acid.

Diminished mucosal prostaglandin production has also been proposed to exist in subsets of patients with duodenal ulcer. Prostaglandins and prostaglandin analogues have been shown to exert cytoprotective effects, to accelerate healing of established duodenal ulcers, and to decrease acid secretion. In the duodenum, locally produced prostaglandins stimulate mucosal bicarbonate secretion. In patients with active duodenal ulceration, gastric mucosal production of prostaglandin E₂ and other prostanoids has been shown to be diminished. An increase in prostanoid synthesis within the gastric mucosa characterizes ulcer healing. Duodenal bicarbonate responses to prostaglandin E₂ are impaired in patients with duodenal ulcer.

Inflammatory responses to *H. pylori* infection are central to the pathogenesis of peptic ulceration. While *H. pylori* infection always induces inflammation, the patterns of response are not uniform. Three major patterns have been recognized.^{8,9} The most common pattern is a mild to moderate inflammation of all regions of the stomach. This form is not associated with major alterations in gastric acidity and most individuals are asymptomatic and do not develop peptic ulceration. Approximately 15% of infected individuals develop an antral-predominant form of gastritis. These individuals exhibit an intense inflammation limited to the antrum without involvement of the mucosa of the gastric corpus. Gastrin

levels are elevated and acid secretion is high. Inhibitory control of gastric acid production is impaired in this form of gastritis. As a result, duodenal and prepyloric ulcers are common. The third form of inflammatory response, occurring in 1% of infected individuals, is least common but most serious. This form is characterized by corpus-predominant gastritis, hypochlorhydria, and gastric atrophy. This form of inflammatory response is considered a precursor state for gastric cancer. Individuals with the third pattern of inflammation demonstrate hypergastrinemia, low acid secretion, and diminished secretion of pepsinogen.

Environmental Factors

NSAIDs have emerged as a significant risk factor for the development of acute ulceration. Although acute mucosal injury caused by NSAIDs is more common in the stomach than in the duodenum, NSAID-induced ulcer complications occur with equal frequency in these two sites. NSAIDs produce a variety of lesions, ranging from hemorrhage, to superficial mucosal erosions, to deeper ulcerations. In the duodenum, it appears likely that invasive NSAID-associated ulcers result from underlying peptic ulcer diathesis compounded by the direct injurious effects of these drugs.

The ulcerogenic actions of NSAIDs have been attributed to their systemic suppression of prostaglandin production. Numerous experimental models have demonstrated the ability of NSAIDs to injure the gastroduodenal mucosa. Ulcers resembling those caused by NSAIDs can be produced experimentally by antibodies to prostaglandins. Conversely, NSAID-associated gastric ulcers can be prevented by the coadministration of prostaglandin analogues. Ulcers associated with NSAIDs usually heal rapidly when the drug is withdrawn, corresponding to the reversal of antiprostaglandin effects. All available NSAIDs appear to pose the hazard of gastroduodenal ulceration. Clinically important ulceration (of both the stomach and duodenum) is estimated by the U.S. Food and Drug Administration to occur at a rate of 2% to 4% per patient-year. The risks inherent with NSAID use appear to be increased by a history of *H. pylori* infection, by cigarette smoking, and by alcohol use. The incidence of NSAID-caused ulcer complications is highest in older patients, as is the attendant mortality rate. Peptic ulcer disease is rare in individuals who are *H. pylori* negative and who are not receiving NSAID medications.

A role of NSAIDs in upper gastrointestinal (GI) hemorrhage is widely recognized. The risk of bleeding is particularly acute for peptic ulceration. In three reports, spanning two decades, NSAIDs were linked to 50% to 75% of bleeding peptic ulcers, one-third of deaths due to hemorrhage, and 30% of hospitalizations.^{10,11} Use of NSAIDs increases the risk of bleeding from peptic ulcer threefold for those under 65 years of age, but by eightfold for individuals over 75 years of age. The odds ratio for bleeding is 13 for patients with a prior history of bleeding ulcer.

Because of the risk of gastrointestinal side effects, a selective class of cyclooxygenase-2 (COX-2) inhibitors was developed for long-term pain relief and anti-inflammatory therapy. Selective COX-2 inhibitors have reduced potential to injure the gastrointestinal mucosa relative to standard NSAIDs.¹¹ Concurrent use of aspirin with COX-2 inhibitors significantly undermines the safety advantages of the COX-2 agents, as does smoking.¹²

DIAGNOSIS

The cardinal feature of duodenal ulceration is epigastric pain. The pain is usually confined to the upper abdomen and is described as burning, stabbing, or gnawing. Unless perforation or penetration into the head of the pancreas has occurred, referral of pain is not common. Many patients report pain on arising in the morning. Ingestion of food or antacids usually provides prompt relief. In uncomplicated cases, abnormal physical findings are minimal. The differential diagnosis is broad and includes a variety of diseases originating in the upper gastrointestinal tract. The most common disorders to be distinguished include nonulcerative dyspepsia, gastric neoplasia, cholelithiasis and related diseases of the biliary system, and both inflammatory and neoplastic disorders of the pancreas. In dyspeptic patients, the principal diagnoses that must be differentiated definitively are peptic ulceration and gastric cancer.

The evaluation of patients with suspected peptic ulceration usually involves endoscopy, the standard against which other diagnostic modalities are measured. Endoscopy is employed because it permits biopsy of the esophagus, stomach, and duodenum. Endoscopy must be recommended with discretion because of associated morbidity (approximately 1 per 5,000 cases) and higher costs.

Duodenal ulcer is characterized by lesions that are erosive to the bowel wall. When viewed endoscopically, the ulcers have a typical appearance. The edges are usually sharply demarcated and the

underlying submucosa is exposed. The ulcer base is often clean and smooth, although acute ulcers and those with recent hemorrhage can demonstrate eschar or adherent exudate. Surrounding mucosal inflammation is common. The most frequent site for peptic ulceration is the first portion of the duodenum, with the second portion less commonly involved. Ulceration of the third or fourth portions of the duodenum is unusual, and occurrence in these sites should arouse suspicion of an underlying gastrinoma. Ulceration in the pyloric channel or the prepyloric area is similar in endoscopic appearance to duodenal ulceration, and ulcers in these areas demonstrate other clinical features similar to duodenal ulcers. Endoscopic demonstration of a duodenal ulcer should prompt mucosal biopsy of the gastric antrum to demonstrate the presence of *H. pylori* and guide subsequent therapy.

The hallmarks of the histologic appearance of duodenal ulcers are chronicity and invasiveness. Chronic injury is suggested by surrounding fibrosis; collagen is deposited in the submucosa during each round of ulcer relapse and healing. The adjacent mucosa often demonstrates evidence of chronic injury with infiltration of acute and chronic inflammatory cells. Gastric metaplasia, in which the duodenum exhibits histologic features of gastric mucosa, is common in the surrounding nonulcerated mucosa. The ulcer can extend for a variable distance through the wall of the duodenum, including the full thickness of the bowel in cases of perforation.

DRUG TREATMENT OF ULCER DISEASE

4 In the absence of active treatment, *H. pylori* infection is lifelong. Spontaneous healing of infected mucosa is very rare, occurring in less than 0.5% per patient-year. Current treatment of peptic ulceration involves a combination of an antisecretory drug, usually a proton pump inhibitor, with antibiotics.¹³ This therapy is rational for most patients who are *H. pylori* positive and results in a high rate of sustained ulcer healing.

A large number of drug regimens have been described, but the most widely used treatment protocols combine a proton pump inhibitor, usually omeprazole, with two antibiotics, usually clarithromycin and metronidazole or amoxicillin. A combination of antibiotics is more effective than one antibiotic alone in almost all series. This triple therapy is administered for 7 or 14 days. Triple-drug therapy is cost effective and associated with a low rate of side effects, low rates of antibiotic resistance, and acceptable levels of patient compliance. *H. pylori* eradication rates of greater than 90% have been reported.

After elimination of *H. pylori*, ulcer recurrence rates reflect the rate of reinfection. In developed countries, reinfection rates of less than 10% at 5 years have been reported. Eradication of *H. pylori* improves quality of life, as measured by symptoms, drug prescriptions, physician visits, and days of missed employment. To date, antibiotic resistance has been low, approximately 18% for clarithromycin, 14% for levofloxacin, and 35% for metronidazole. Resistance to amoxicillin has been close to zero.¹⁴

HISTAMINE-RECEPTOR ANTAGONISTS

Histamine, released into the interstitial fluid by cells in the fundic mucosa, diffuses to the mucosal parietal cell. Histamine stimulates acid production by occupying a membrane-bound receptor and activating parietal cell adenylate cyclase. Histamine is released in response to a number of physiologic stimuli; blockade of histamine receptors inhibits most forms of stimulated acid secretion in humans. Parietal cell histamine receptors are classified as H₂ receptors because they are activated by agonists such as 4-methylhistamine and are selectively blocked by agents such as cimetidine. Some H₂-receptor antagonists also possess nongastric actions by binding to androgen receptors, by interacting with the hepatic microsomal oxidase system, and by crossing the blood–brain barrier. All clinically useful gastric histamine receptor antagonists are of the H₂ type.

H₂-receptor antagonists bind competitively to parietal cell H₂ receptors to produce a reversible inhibition of acid secretion. An enormous worldwide experience has accumulated with the use of H₂-receptor antagonists. The agents are effective and safe when used in the treatment of peptic ulcer. The various compounds have similar efficacy in terms of ulcer healing when used in doses that produce similar reductions in acid output. It is clear that H₂-receptor blockers do not affect the underlying ulcer diathesis; if H₂-receptor antagonists are stopped, recurrent ulceration occurs in more than half of patients within 1 year. The current understanding of the role of *H. pylori* in ulcer pathogenesis has changed the role of H₂-receptor antagonists from primary therapy to that of a substitute for proton

pump inhibitors in conjunction with antibiotic treatment.

PROTON PUMP BLOCKERS

Acid secretion by the gastric parietal cells is due to the active transport of hydrogen ions from the parietal cell cytoplasm into the secretory canaliculus in exchange for potassium. Because this so-called *proton pump* is tissue specific, being present only in gastric mucosa, its blockade would be expected to have minimal effects on nongastric functions. Omeprazole is representative of a family of compounds that selectively block the parietal cell proton pump.

Omeprazole is a weak base, with a pKa of approximately 4. The drug is nonionized and lipid soluble at neutral pH, but it becomes ionized and activated at a pH of less than 3. In its activated state, omeprazole binds to the membrane-bound H⁺-K⁺-adenosine triphosphatase (ATPase) of the parietal cell. Because the compound is a weak base, omeprazole accumulates selectively within the acidic environment of the parietal cell secretory canaliculus; 4 hours after administration, the drug is detectable in appreciable quantities only in the gastric mucosa. If enough drug is administered to occupy all parietal cell-binding sites, an acidity can be produced. Omeprazole, in doses from 20 to 30 mg, causes nearly complete inhibition of stimulated gastric acid secretion within 6 hours. At 24 hours after drug administration, a 60% to 70% reduction in acid secretion persists.

Repeated daily dosing with omeprazole results in increasing inhibitory action on gastric secretion and thus in decreased intragastric degradation of the drug. Acid suppression stabilizes after approximately 3 days. Because of tissue accumulation, the secretory actions of omeprazole do not correlate with plasma levels. Several studies have demonstrated a significant inhibition of peak acid output, marked relief of epigastric pain, and decreased use of supplemental antacids during omeprazole therapy. Direct comparisons with H₂-receptor antagonists have generally favored omeprazole in terms of pain relief and rate of ulcer healing.

OPERATIVE TREATMENT OF ULCER DISEASE

Surgical Goals

Operative intervention is reserved for the treatment of complicated ulcer disease. Three complications are most common and constitute the indications for peptic ulcer surgery – hemorrhage, perforation, and obstruction. The first goal in the surgical treatment of the complications of ulcer disease is treatment of coexisting anatomic complications, such as pyloric stenosis or perforation. The second major goal should be patient safety and freedom from undesirable chronic side effects. To achieve these goals, the gastric surgeon can direct therapy through endoscopic or operative means, the appropriate choice depending on the clinical circumstances.

Operative Procedures

A number of operative procedures have been used to treat peptic ulcer, but with decreasing frequency in the past decade. There is currently no indication for surgical treatment of uncomplicated ulcer disease. Operative treatment of gastric outlet obstruction has decreased by approximately 50%. Most surgical patients are now treated emergently for the complications of bleeding or perforation.

Three procedures – truncal vagotomy and drainage, truncal vagotomy and antrectomy, and proximal gastric vagotomy – were widely used in the past in the operative treatment of peptic ulcer disease. With increasing frequency, surgical therapy of peptic ulcer is directed exclusively at correction of the immediate problem (e.g., closure of duodenal perforation) without gastric denervation. The underlying ulcer diathesis is then addressed after surgery by antibiotic therapy directed at *H. pylori*. This approach is applicable to most patients with peptic ulcer undergoing emergent operation and implies a very limited role for vagotomy in the future.

Division of both vagal trunks at the esophageal hiatus – truncal vagotomy – denervates the acid-producing fundic mucosa as well as the remainder of the vagally supplied viscera (Fig. 45-1). Because denervation impedes normal pyloric coordination and can result in impairment of gastric emptying, truncal vagotomy must be combined with a procedure to eliminate pyloric sphincteric function. Usually, gastric drainage is ensured by performance of a pyloroplasty (Fig. 45-2).

When truncal vagotomy is combined with resection of the gastric antrum there is a further reduction

in acid secretion, presumably by removing antral sources of gastrin. The limits of antral resection are usually defined by external landmarks, rather than the histologic transition from fundic to antral mucosae. The stomach is divided proximally along a line from a point above the incisura angularis to a point along the greater curvature midway from the pylorus to the gastroesophageal junction. Restoration of gastrointestinal continuity by a gastroduodenostomy is termed a Billroth I reconstruction. A Billroth II procedure uses a gastrojejunostomy ([Fig. 45-3](#)).

Figure 45-1. Truncal vagotomy and proximal gastric vagotomy. **A:** With truncal vagotomy, both nerve trunks are divided at the level of the diaphragmatic hiatus. **B:** Proximal gastric vagotomy involves division of the vagal fibers that supply the gastric fundus. Branches to the antropyloric region of the stomach are not transected, and the hepatic and celiac divisions of the vagus nerves remain intact.

Figure 45-2. Pyloroplasty formation. **A:** A Heineke–Mikulicz pyloroplasty involves a longitudinal incision of the pyloric sphincter followed by a transverse closure. **B:** The Finney pyloroplasty is performed as a gastroduodenostomy with division of the pylorus. **C:** The Jaboulay pyloroplasty differs from the Finney procedure in that the pylorus is not transected.

Figure 45-3. Antrectomy involves resection of the distal stomach (pink area in inset). Restoration of gastrointestinal continuity may be accomplished as a Billroth I gastroduodenostomy (A) or Billroth II gastrojejunostomy (B) reconstruction.

Physiologic Consequences of Operation

Division of efferent vagal fibers directly affects acid secretion by reducing cholinergic stimulation of parietal cells. In addition, vagotomy also diminishes parietal cell responsiveness to gastrin and histamine. Basal acid secretion is reduced by approximately 80% in the immediate postoperative period. Acid secretion increases slightly within months of surgery but remains unchanged thereafter. The maximal acid output in response to exogenously administered stimulants such as pentagastrin is reduced by approximately 70% in the early period after surgery. After 1 year, pentagastrin-stimulated maximal acid output rebounds to 50% of prevagotomy values but remains at this level on subsequent testing. Acid secretion due to endogenous stimulation by a liquid meal is reduced by 60% to 70% relative to normal subjects.

The inclusion of antrectomy with truncal vagotomy causes further reductions in acid secretion. Pentagastrin-stimulated maximal acid output is reduced by 85% relative to values recorded before surgery. Little rebound in acid secretion occurs with the passage of time.

Operations that involve vagotomy alter gastric emptying. Proximal gastric denervation abolishes vagally mediated receptive relaxation. Thus, for any given volume ingested, the intragastric pressure rise is greater and the gastroduodenal pressure gradient is higher than that in normal subjects. As a result, emptying of liquids, which depends critically on the gastroduodenal pressure gradient, is accelerated after proximal gastric vagotomy. Because nerve fibers to the antrum and pylorus are preserved, the function of the distal stomach to mix and triturate solid food is preserved, and emptying of solids is nearly normal in patients who have undergone proximal gastric vagotomy. Truncal vagotomy affects the motor activities of both the proximal and distal stomach. Solid and liquid emptying rates are usually increased when truncal vagotomy is accompanied by pyloroplasty.

Dumping, a postprandial symptom complex of abdominal discomfort, weakness, and vasomotor symptoms of sweating and dizziness, occurs in 10% to 15% of patients with truncal vagotomy and antrectomy in the early postoperative period and is chronically disabling in 1% to 2%. After truncal vagotomy and pyloroplasty, dumping is present initially in 10% and remains severe in approximately

1%. Permanent symptoms of dumping are rare after proximal gastric vagotomy. The incidence of diarrhea, which is presumably caused by denervation of the pylorus and small bowel and by elimination of pyloric function, parallels the incidence of dumping after truncal vagotomy and antrectomy or pyloroplasty. Persistent or disabling diarrhea is present in less than 1% of patients after proximal gastric vagotomy.

Most prospective surgical series were reported in the era before the pathogenic role of *H. pylori* was appreciated. With appropriate use of postoperative antimicrobials directed against *H. pylori*, ulcer recurrence rates are currently much lower than historical standards. Although recurrence rates (without *H. pylori* treatment) as low as 5% have been reported, a more generally accepted figure is 10%. This rate is similar to that of reinfection with *H. pylori* after its successful eradication. The reported ulcer recurrence rates after proximal gastric vagotomy can be adversely affected by the inclusion of prepyloric and pyloric channel ulcers.

Hemorrhage

5 Hemorrhage is the leading cause of death associated with peptic ulcer, and the incidence of this complication has not changed since the introduction of H₂-receptor antagonists. The lifetime risk of hemorrhage for patients with duodenal ulcer who have not had surgery and who do not receive continuing maintenance drug therapy approximates 15% at 5 years.¹⁵ Most hemorrhages occur during the initial episode of ulceration or during a relapse, and patients who have hemorrhaged previously have a higher risk of bleeding again. Continued or recurrent bleeding occurs in 20% to 30% of patients, and when this happens, mortality varies between 10% and 40%. Patients with recurrent hemorrhage and elderly patients are at greatest risk of death, and these two groups should be resuscitated vigorously, investigated promptly, and treated aggressively.^{16,17}

The contemporary risk of mortality from bleeding ulcer approximates 10% to 20%. Operative risk is increased in patients who have shock at admission, recurrent bleeding, delay in operative intervention, or coexisting medical illnesses. Surgical delay may lead to recurrent hypovolemia and, subsequently, multisystem organ failure.

Upper gastrointestinal endoscopy is the appropriate initial diagnostic test when hemorrhage from duodenal ulceration is suspected. Endoscopy can correctly determine the site and cause of bleeding in more than 90% of patients. An ulcer should be accepted as the bleeding source only if it has one of the stigmata of active or recent hemorrhage. Active hemorrhage is defined by an arterial jet, active oozing, or oozing beneath an adherent clot. The signs of recent hemorrhage include an adherent clot without oozing, an adherent slough in the ulcer base, or a visible vessel in the ulcer. The ability of these endoscopic findings to accurately predict recurrent hemorrhage has been extensively validated. Approximately 30% of patients who have stigmata of recent hemorrhage experience rebleeding, and most of the patients who experience recurrent hemorrhage require emergency treatment. These stigmata are not sufficiently accurate to be used alone as indications for surgery. Rather, they serve as a warning that aggressive therapy is needed and close follow-up mandatory. The occurrence of hypovolemic shock, rebleeding during hospitalization, and a posteroinferior location of the ulcer are additional clinical features that have been associated with increased risks of recurrent bleeding. A recent study suggests that rebleeding risk in excess of 30% justifies second-look endoscopy as a means to anticipate, and thus preemptively treat, ulcers at highest risk of recurrent hemorrhage.¹⁸ The role of gastric acidity as a cause for in-hospital rebleeding appears to be inconsequential, and reduction of acid secretion by H₂-receptor antagonists or omeprazole is not sufficient to prevent recurrent hemorrhage.

The ability to visualize bleeding duodenal ulcers endoscopically has led to development of methods to treat hemorrhage endoscopically. There are many different methods of endoscopic therapy, but the most established consist of thermal coagulation, injection of alcohol, or sclerosants. Thermal coagulation can be achieved by bipolar electrocoagulation or direct application of heat through a heater probe. Injection of epinephrine into the base of the bleeding ulcer is also effective in control of ulcer hemorrhage.

Proof of efficacy, in the form of lowered rebleeding rates and avoidance of operation, has been convincingly demonstrated for all of these methods of endoscopic hemostasis. The analysis of reports of endoscopic treatment of hemorrhage is complicated by the 70% rate of spontaneous, although sometimes temporary, cessation of bleeding without intervention. In addition to endoscopic stigmata, hemodynamic instability, need for continuing transfusion, red stool or hematemesis, age older than 60 years, and serious medical comorbidity are clinical features that mandate endoscopic therapy. Rebleeding during hospitalization and the endoscopic findings of visible vessel, oozing, or bleeding

associated with an adherent clot are other indications for endoscopic hemostasis. Ulcers with clean bases require no treatment. Failure of endoscopic hemostasis is usually due to inaccessibility because of scarring, to rapid active bleeding obscuring the endoscopic view, or to an adherent clot. Patients treated endoscopically should be observed closely for further hemorrhage. Patients who rebleed within 72 hours of initial endoscopic control may be successfully retreated without increasing the risk of mortality.¹⁹

The efficacy of endoscopy is dependent on timing. Early endoscopy correctly identifies patients at low risk for recurrent hemorrhage and permits safe avoidance of hospitalization. Early endoscopy also benefits high-risk patients by directing active hemostatic therapy. Patients treated in this way have been demonstrated to have fewer episodes of rebleeding, lower rates of operation, and shorter hospitalizations.

Table 45-3 lists situations in which operative intervention is appropriate. The need for emergency surgery significantly increases surgical risks; mortality rates are increased approximately 10-fold. Operative therapy should consist of duodenostomy with direct ligation of the bleeding vessel in the ulcer base.

INDICATIONS/CONTRAINDICATIONS

Table 45-3 Situations in Which Operative Intervention is Appropriate

Massive hemorrhage leading to shock or cardiovascular instability
Prolonged blood loss requiring continuing transfusion
Recurrent bleeding during medical therapy or after endoscopic therapy
Recurrent hemorrhage requiring hospitalization

Postoperatively, patients should receive antibiotics directed against *H. pylori*. This treatment paradigm is based on the observation that peptic ulcer hemorrhage recurs in 20% of patients in whom *H. pylori* is not eradicated, whereas rebleeding is reduced to 3% in patients who receive *H. pylori* eradication therapy (Algorithm 45-1).²⁰ The studies that support this practice were not specifically designed to evaluate postoperative hemorrhage, but the results are so definitive that they support this application (Fig. 45-4).

Perforation

The lifetime risk for perforation in patients with duodenal ulceration who do not receive therapy approximates 10%. In contrast, ulcer perforation is unusual if initial ulcer healing has been achieved.

Perforation of a duodenal ulcer is usually accompanied by sudden and severe epigastric pain. The pain, caused by the spillage of highly caustic gastric secretions into the peritoneum, rapidly reaches peak intensity and remains constant. Radiation to the right scapular region is common because of right subphrenic collection of gastric contents. Occasionally, pain is sensed in the lower abdomen if gastric contents travel caudally through the paracolic gutter. Peritoneal irritation is usually intense and most patients avoid movement to minimize discomfort.

Physical examination reveals low-grade fever, diminished bowel sounds, and rigidity of the abdominal musculature. Usually, upright abdominal radiographs reveal pneumoperitoneum, but up to 20% of perforated ulcers do not show free intraperitoneal air. Computed tomography of the abdomen is very sensitive for demonstrating perforation if pneumoperitoneum is not demonstrated but perforation is still suspected.

Figure 45-4. Probability of freedom from recurrent hemorrhage according to posttreatment *H. pylori* status.

Algorithm 45-1. Treatment of bleeding duodenal ulceration.

Although occasional reports have described the nonoperative treatment of this complication, perforation remains a strong indication for surgery in most circumstances. Laparotomy or laparoscopy affords the opportunity to relieve intraperitoneal contamination and to close the perforation (Fig. 45-5).

Signs of antecedent duodenal ulceration, in terms of history of prior symptoms and anatomic evidence of duodenal scarring, should be sought. A lack of antecedent symptoms is not protective. Reports suggest that patients without antecedent symptoms are also at risk for recurrent ulceration. By 5 to 6 years, symptomatic ulcer recurrence in patients with acute ulcer perforation is similar to that for patients with chronic disease. Before the role of *H. pylori* was appreciated, simple omental closure of duodenal perforation resulting from chronic ulceration did not provide satisfactory long-term results; up to 80% of patients so treated had recurrent ulceration, and 10% experienced reperforation if untreated. Approximately four-fifths of all patients with perforation have *H. pylori* infestation and therefore are at risk of recurrent disease.

The mortality of emergent ulcer operations is most clearly correlated with the following circumstances: preoperative shock, coexisting medical illness, and presence of perforation for more than 48 hours.²¹ Mortality increases progressively with the number of prognostic variables present – the so-called Boey Score – being 0%, 10%, 45%, and 100% with zero to three positive. Mortality with perforated peptic ulcer disease has also been correlated with the American Society of Anesthesiology (ASA) score and the Peptic Ulcer Perforation (PULP) score.²²

6 Current reports advocate omental patch closure only, often laparoscopically, with postoperative

anti-*H. pylori* therapy. This approach presumes that most duodenal ulcers are caused by *H. pylori*, that secure closure of the perforation can be obtained, and that further surgical therapy will be obviated by the effects of medical therapy. Minimally invasive approaches are becoming standard practice.

Figure 45-5. Omental patching of perforated duodenal ulcer.

Three meta-analyses of surgical treatment of perforated peptic ulcer have compared open surgical therapy with laparoscopic approaches.^{23–25} In terms of operative time, there is no clear superiority of one approach over the other, but trials reported after 2001 have favored laparoscopic repair. While in-hospital analgesic use is less in laparoscopically treated patients, the more important variable of hospital length of stay was not significantly shorter for these patients. Overall rates of postoperative complications were not statistically different between the two approaches. A lower rate of wound infection in the laparoscopic group approached significance. Return to normal daily activities and work favored the laparoscopic group. The pooled estimate of mortality favored laparoscopic repair. Thirty-day mortality risk approximates 15%.²⁶ Septic complications, organ space infection, and prolonged ventilation are leading causes of postoperative morbidity.²⁷

Obstruction

Gastric outlet obstruction can occur acutely or chronically in patients with duodenal ulcer disease. Acute obstruction is caused by edema and inflammation associated with ulcers in the pyloric channel and the first portion of the duodenum. Pyloric obstruction is suggested by recurrent vomiting, dehydration, and hypochloremic alkalosis due to loss of gastric secretions. Acute gastric outlet obstruction is treated with nasogastric suction, rehydration, and intravenous administration of antisecretory agents. In most instances, acute obstruction resolves with such supportive measures within 72 hours.

Repeated episodes of ulceration and healing can lead to pyloric scarring and a fixed stenosis with chronic gastric outlet obstruction.

Upper endoscopy is indicated to confirm the nature of the obstruction and to exclude neoplasm. Endoscopic hydrostatic balloon dilatation of pyloric stenoses can also be attempted at this time (Fig. 45-6). Approximately 85% of pyloric stenoses are amenable to balloon dilatation. Only 40% of patients with gastric stenoses have sustained improvement by 3 months after balloon dilatation. Recurrent stenoses are presumably due to residual scarring in the pyloric channel. Thus, although pyloric dilatation is occasionally palliative, in most cases operative correction is required.

Operative management of gastric outlet obstruction should be focused on relief of the anatomic abnormality. Antrectomy has been used with success in this circumstance, with low ulcer recurrence rates and with satisfactory restoration of gastric emptying.

GASTRIC ULCER

Benign gastric ulcers are a form of peptic ulcer disease, occurring with one-third the frequency of benign duodenal ulceration. In the United States, gastric ulcer is somewhat more common in men than in women and occurs in a patient cohort approximately 10 years older than for duodenal ulceration.

Endoscopic Diagnosis

Upper gastrointestinal endoscopy is the preferred method for diagnosing gastric ulceration. The ulcer base in benign disease is commonly smooth and flat and often covered by a gray, fibrous exudate. The margin is usually slightly raised, erythematous, and friable. Differentiation of benign and malignant gastric ulcers is reliably made only by histologic examination. Visual endoscopic differentiation of benign from malignant ulcers is not reliable. All gastric ulcers should have multiple biopsies taken from the perimeter of the lesion. The addition of lesional brushings to biopsy increases diagnostic accuracy to approximately 95%.

Benign gastric ulcers may occur in any location in the stomach, but approximately 60% are located along the lesser curvature proximal to the incisura angularis. Less than 10% of benign gastric ulcers are located on the greater curvature. Virtually all gastric ulcers lie within 2 cm of the histologic transition between fundic and antral mucosa. With increasing age, this mucosal transition zone moves proximally along the lesser curvature. Movement of this transition zone is reflected by the greater prevalence of proximal ulcers in elderly patients.

As with benign duodenal ulceration, *H. pylori* plays a central role in the pathogenesis of benign gastric ulcers.²⁸ Benign gastric ulcers associated with *H. pylori* respond to antibiotic therapy at a rate equivalent to that of duodenal ulceration. The recurrence rate of ulcerations in these patients after *H. pylori* eradication is equal to the rate of reinfection.

A strong association of benign gastric ulceration with the use of NSAIDs has been recognized. Cigarette smoking is associated with development of gastric ulceration, and continued smoking impedes medical therapy. Gastric and duodenal ulcers have been noted in patients receiving hepatic artery chemotherapy in whom improper placement of the catheter permits perfusion of gastric and duodenal mucosae. A variety of agents, including 5-fluorouracil, cisplatin, doxorubicin, and mitomycin C, have been implicated.

Figure 45-6. Schematic representation of balloon dilatation of pyloric stenosis.

Therapy

The primary therapy for benign gastric ulceration in most patients is antimicrobial treatment of *H. pylori* infection. The treatment protocols are similar to those used for benign duodenal ulceration. For many patients, cessation of NSAID therapy is also required.

Indications for surgical treatment of gastric ulcer include hemorrhage, perforation, failure of a recurrent ulcer to respond to medical therapy, and inability to exclude malignant disease.

For benign gastric ulcers, the elective operation of choice is usually a distal gastrectomy with gastroduodenal (Billroth I) anastomosis. The ulcer should be included in the gastrectomy specimen. With this approach, operative mortality rates of 2% to 3%, with ulcer recurrence rates of less than 5%, have been reported. Because benign gastric ulcers are not associated with gastric acid hypersecretion,

inclusion of vagotomy is not necessary.

The occurrence of a gastric ulcer near the gastroesophageal junction represents a difficult surgical problem. When possible, the ulcer should be excised. This usually requires a distal gastrectomy with an extension along the lesser curvature near the esophageal wall and reconstruction with gastrojejunostomy.

Emergency operations performed for hemorrhage or perforation require ulcer excision. Distal gastrectomy, performed with gastroduodenal reconstruction, is usually the procedure of choice. Operative mortality rates average 10% to 20% in the presence of hemorrhage or perforation.

POSTGASTRECTOMY SYNDROMES

A number of syndromes have been described that are associated with distressing symptoms after gastric operations performed for peptic ulcer or gastric neoplasm. The occurrence of severe postoperative symptoms is fortunately low, perhaps 1% to 3% of cases, but the disturbances can be disabling. The two most common postgastrectomy syndromes, categorized according to predominant manifestation, are dumping and alkaline reflux gastritis.

Dumping

The term *dumping* denotes a clinical syndrome with both gastrointestinal and vasomotor symptoms. The precise cause of dumping is not known but is believed to relate to the unmeted entry of ingested food into the proximal small bowel after vagotomy and either resection or division of the pyloric sphincter. Early dumping symptoms occur immediately after a meal and include nausea, epigastric discomfort, borborygmi, palpitations, and, in extreme cases, dizziness or syncope. Late dumping symptoms follow a meal by 1 to 3 hours and can include reactive hypoglycemia in addition to the aforementioned symptoms.

Although a relatively large number of patients experience mild dumping symptoms in the early postoperative period, minor dietary alterations and the passage of time bring improvement in all but approximately 1%. The somatostatin analogue octreotide has been reported to improve dumping symptoms when 50 to 100 mg is administered subcutaneously before a meal. The beneficial effects of somatostatin on the vasomotor symptoms of dumping are postulated to be due to pressor effects of the compound on splanchnic vessels. In addition, somatostatin analogues inhibit the release of vasoactive peptides from the gut, decrease peak plasma insulin levels, and slow intestinal transit, all effects that might be expected to ameliorate dumping symptoms. Octreotide administration before meal ingestion has been shown to prevent changes in pulse, systolic blood pressure, and packed red cell volume during early dumping and blood glucose levels during late dumping.

Alkaline Reflux Gastritis

The term *alkaline reflux gastritis* should be reserved for patients who demonstrate the clinical triad of postprandial epigastric pain often associated with nausea and vomiting, evidence of reflux of bile into the stomach, and histologic evidence of gastritis. One or more of these findings occur transiently in 10% to 20% of patients after gastric resection, but they persist in only 1% to 2%.

The differential diagnosis for a patient with postoperative epigastric pain includes recurrent ulceration, biliary and pancreatic disease, afferent loop obstruction, and esophagitis in addition to alkaline reflux gastritis. Serum gastrin measurements should be determined to exclude Zollinger–Ellison syndrome and retained gastric antrum. Endoscopic examination is essential to exclude recurrent ulcer.

Endoscopically, the gastric mucosa appears red, friable, and edematous. Gastric inflammation is patchy and nonulcerative. Histologic examination shows mucosal and submucosal edema and infiltration of acute and chronic inflammatory cells into the lamina propria. Glandular atrophy and intestinal metaplasia are frequent accompaniments.

No perfect solution to alkaline reflux gastritis exists. H₂-receptor antagonists, proton pump inhibitors, bile acid chelators, and dietary manipulations have not been demonstrated definitely to be beneficial. The only proved treatment for alkaline reflux gastritis is operative diversion of intestinal contents from contact with the gastric mucosa. The most common surgical procedure used for this purpose is a Roux-en-Y gastrojejunostomy with an intestinal limb of 50 to 60 cm constructed to prevent reflux of intestinal contents (Fig. 45-7). This procedure is effective in eliminating bilious vomiting (nearly 100%), but recurrent or persistent pain is reported in up to 30% of patients, and up to 20% of patients are troubled

with postoperative delayed gastric emptying.

STRESS GASTRITIS

7 Major trauma accompanied by shock, sepsis, respiratory failure, hemorrhage, or multiorgan injury is often accompanied by acute stress gastritis. Acute stress gastritis is particularly prevalent after thermal injury with greater than 35% total surface area burned.²⁹ Multiple superficial ulcerations and erosions are noted in the proximal, acid-secreting portion of the stomach, with fewer lesions in the antrum and only rare ulcerations in the duodenum.

The most sensitive diagnostic test for stress ulceration is endoscopic examination. If patients are examined within 12 hours of the onset of injury, acute mucosal ulcerations may be observed that appear as multiple, shallow areas of erythema and friability, often accompanied by focal hemorrhage. The lesions are progressive during the first 72 hours after injury. When lesions are examined histologically, they are seen to consist of coagulation necrosis of the superficial endothelium with infiltration of leukocytes into the lamina propria. Chronic disease, characterized by fibrosis and scarring, is not observed. With resolution of the underlying injury or sepsis, healing is accompanied by mucosal restitution and regeneration.

Clinical observations and a large number of experimental studies suggest that mucosal ischemia is the central event underlying the development of stress gastritis. In clinical practice, most patients who contract stress gastritis do so after an episode of sepsis, hemorrhage, or cardiac dysfunction accompanied by shock. Experimental studies that cause depletion of high-energy phosphate compounds such as ATP predispose to the development of stress gastritis. Luminal gastric acid secretion, although not the sole cause of stress gastritis, appears to be a necessary concomitant process. A number of experimental observations suggest that a critical concentration of luminal acid is required to initiate injury in the setting of mucosal ischemia. The fall in mucosal energy supply permits proton back-diffusion into the mucosa; the resultant decrease in mucosal pH exacerbates ischemic damage.

Figure 45-7. Conversion of Billroth II gastrojejunostomy to Roux-en-Y gastrojejunostomy. The afferent limb is divided (A) and intestinal continuity is reestablished by anastomosis 50 to 60 cm downstream from the original gastrojejunostomy (B).

Clinical risk factors that predict development of stress gastritis include adult respiratory distress syndrome, multiple long-bone fractures, a major burn over 35% of the body surface, transfusion requirement above 6 units, hepatic dysfunction, sepsis, hypotension, and oliguric renal failure. Scoring systems of critical illness, exemplified by the Acute Physiology and Chronic Health Evaluation (APACHE) system, accurately predict risk for acute stress gastritis.

The major complication of stress gastritis is hemorrhage. Admission to an intensive care unit is not an independent risk factor for bleeding. However, the development of respiratory failure or coagulopathy (platelet count less than 50,000/mm³, international normalized ratio (INR) >1.5, or partial thromboplastin time (PTT) greater than two times normal) imparts the greatest risk for hemorrhage.

Diagnosis

Clinical studies that use bloody nasogastric discharge as a sign of stress gastritis probably underestimate its incidence in critically ill patients. Conversely, studies based on endoscopy overestimate the incidence of clinically important stress gastritis. In one endoscopically controlled study, 100% of patients with life-threatening injuries had evidence of gastric erosions by 24 hours. Severely burned patients have endoscopic evidence of gastric erosions in greater than 90% of cases, whereas significant upper gastrointestinal hemorrhage occurs in between 25% and 50% of patients with burn wound infection.

Treatment and Prophylaxis

Critically ill patients are at risk for development of acute stress gastritis. Because hemorrhage associated with stress gastritis significantly increases mortality, these patients should be treated prophylactically.²⁹⁻³¹ Seven randomized, controlled trials have compared H₂-receptor antagonists with proton pump inhibitors in prophylaxis of bleeding from stress ulceration.²⁹ The consensus of these studies is that proton pump inhibitors are more effective at maintaining gastric pH above 4.0, but no convincing data exist that one agent is superior to the other in prevention of clinically important bleeding. Stress ulcer prophylaxis with these agents is associated with colonization of the upper GI tract with potentially pathogenic gram-negative organisms. No statistically significant differences in incidence of pneumonia have been noted between H₂-receptor antagonists and proton pump inhibitors when used for stress ulcer prophylaxis. H₂-receptor antagonists are involved in more drug-drug interactions due to inhibitory effects on the cytochrome oxidase system. Prolongation of protime may be noted in patients receiving coumadin. Increased plasma concentrations of diazepam, propranolol, nifedipine, and several antibiotics may also be noted in patients receiving H₂-receptor antagonists.

Early enteral feeding was first introduced as a component of burn care. Enteral feeding was designed to address the hypermetabolic state that develops after burn injury and to prevent visceral protein loss due to catabolic metabolism. Enteral nutrition has also been demonstrated to prevent bacterial translocation across the intestinal wall. In addition, enteral nutrition has been noted to maintain intragastric pH >3.5, suggesting that this modality may be used to prevent gastric hemorrhage from stress ulceration. In burn patients, early enteral feeding decreases upper GI hemorrhage, effects that are not potentiated by the addition of H₂-receptor antagonists. It seems likely that early enteral feeding will become widely employed in critically ill surgical patients, beyond those with thermal injury, as a primary modality for stress ulcer prophylaxis.

Chapter 46

Management of Obesity

Robert W. O'Rourke

Key Points

- 1 Obesity is defined and categorized using body mass index (BMI, weight [kg]/height [m]²) based on World Health Organization definitions.
 - 2 BMI directly correlates with the risk of multiple metabolic diseases and long-term mortality.
 - 3 Lifestyle interventions as treatment for obesity, including diet, exercise, and psychological therapy, are of limited efficacy; evolving strategies directed toward environmental manipulation demonstrate potential.
 - 4 Current pharmacotherapy for obesity includes a wide range of agents that act via multiple mechanisms, are prone to side effects, and are of limited efficacy; active research in pharmacotherapy for obesity holds significant promise.
 - 5 Bariatric surgery is highly efficacious in treating obesity and metabolic disease, and includes a wide range of procedures that have evolved over decades.
 - 6 Current dominant bariatric surgery operations include gastric bypass, sleeve gastrectomy, and gastric banding.
 - 7 Classic mechanisms of action of bariatric surgery include restriction of caloric intake and malabsorption of ingested calories, but evolving data suggest that other mechanisms predominate, including but not limited to alterations in gut and satiety hormone homeostasis, bile acid metabolism, and enteroenteric and enterocentral nervous systemic communications.
-

DIAGNOSIS AND EPIDEMIOLOGY

Obesity and Metabolic Disease

Excess adipose tissue is the defining feature of obesity, and metabolic disease arises in adipose tissue. Metabolic disease is diverse, involving every organ system. The correlation between obesity and metabolic disease, while strong, is not perfect – some patients develop metabolic disease at low body weight, while others who are very obese are protected. Visceral adiposity imparts greater risk than subcutaneous adiposity, and heterogeneity of visceral and subcutaneous adiposities partly explains the imperfect correlation between obesity and metabolic disease. Lean patients also develop metabolic disease, albeit less frequently than the obese, demonstrating that nonadipose tissue-based mechanisms contribute to metabolic disease as well. It is beyond the scope of this chapter to discuss the wide spectrum of specific treatment strategies for individual metabolic diseases. Rather, we will discuss the treatment of obesity itself, the goal of which is reduction in adipose tissue mass, because despite the variable relationship between body weight and metabolic dysfunction, in the vast majority of patients, regardless of initial weight, weight loss has beneficial effects on virtually all metabolic diseases. Treatment options for obesity may be broadly divided into medical and surgical approaches.

Diagnosis

1 Body mass index (BMI, weight [kg]/height [m]²) is the primary metric used to define obesity. Originally devised in the 19th century as a general measure of human body habitus, BMI was coopted in the 1940s by the insurance industry and used to stratify humans into high- and low-risk subpopulations based on actuarial data for the purpose of setting life insurance rates. The medical community subsequently used BMI to estimate risk of morbidity and mortality. Much debate exists regarding the appropriate BMI cutoff points for optimal health, with various health and professional organizations setting different values. World Health Organization (WHO) definitions, set in 1995 and agreed upon by the U.S. Centers for Disease Control (CDC), are most commonly utilized and define overweight as BMI

> 25 and < 30 and obesity as BMI ≥ 30 , and categorize obesity into classes 1 (BMI 30 to 34.9), 2 (BMI 35 to 39.9), and 3 (BMI ≥ 40).¹

2 BMI correlates with long-term mortality and metabolic disease in a J-shaped curve, the nadir of which is debated, but may be as low as 20 or as high as 25.² BMI in the obese range (≥ 30) is clearly associated with an increased risk in long-term mortality and multiple metabolic diseases relative to BMI < 30. For individuals with BMI 40 to 50, this risk translates into a 10-year decrease in life expectancy. In contrast to obesity, data demonstrating a correlation between overweight BMI and health risk are conflicting. Analyses are complicated by numerous confounding variables including but not limited to gender, age, ethnicity, smoking, cancer, and diabetes. In addition, the choice of control/referent group alters outcomes; for example, the correlations between overweight BMI and clinical outcomes weaken significantly and may be masked when referent groups span a larger BMI range (e.g., 18 to 25) relative to comparison with referent groups spanning a narrow BMI range (e.g., 21 to 23). Despite these conflicting data, the preponderance of evidence suggests that BMI in the overweight range is associated with an increased risk of long-term mortality, albeit lower than the risk associated with BMI in the obese range.³ Furthermore, mortality aside, compelling data demonstrate that overweight BMI is associated with an increased risk of cardiovascular disease, diabetes, and other metabolic diseases, and is associated with an increased risk of future progression to frank obesity with its attendant risks. Taken together, these observations suggest that overweight should be considered a serious health risk and a predecessor to obesity.

These complex data demonstrate that BMI is not a perfect measure of adiposity. Indeed, muscular athletes may have BMI within the obese range despite low body fat levels and an absence of metabolic disease, while elderly people with a paucity of muscle mass may have low BMI despite increased adiposity and metabolic disease. Ethnic differences further confound the predictive power of BMI, as certain ethnicities, for example Asians, develop metabolic disease at lower BMI, prompting the WHO in 2004 to propose BMI cutoffs of 23 and 27.5 for overweight and obesity respectively in Asians. In certain subpopulations, including patients with heart failure, renal failure, and other chronic diseases, overweight and obesity are associated with decreased mortality, a phenomenon termed the “obesity paradox.”⁴

These observations have led to a search for other measures of adiposity. Waist circumference and waist-hip ratio are easily measured and in many studies correlate more accurately with metabolic disease than BMI, reflecting the disproportionate effect of visceral adiposity on metabolic disease.⁵ Water displacement, dual-energy x-ray absorptiometry scanning, double-labeled isotope water measurement, bioelectrical impedance analysis, and quantitative magnetic resonance imaging may provide more accurate measures of adiposity and better predict metabolic disease, but have not gained widespread acceptance due to cost and complexity. Despite its limitations, BMI remains the most commonly used metric for obesity.

Epidemiology, Disease Burden

Human obesity has existed for millennia as evidenced by prehistoric figurines of obese humans (e.g., Venus of Willendorf) and periodic concerns regarding past obesity “epidemics” over the past two centuries. Nonetheless, the worldwide prevalence of overweight and obesity has increased dramatically over the past 50 years. BMI, like many clinical characteristics, spans a bell curve. Three large US epidemiologic datasets, the National Health and Nutrition Examination Survey (NHANES), the National Health Interview Survey (NHIS), and the Behavioral Risk Factor Surveillance System (BRFSS), demonstrate similar trends, with a rightward shift of the BMI bell curve over the past three decades, mean BMI increasing from 25.5 in the 1970s to 28.5 in 2005, and the prevalence of obesity more than doubling in the same interval.⁶ The CDC reports that as of 2010, 69% of US adults were overweight or obese, and 36% of US adults and 17% of US children were obese.⁷ Evidence suggests that the prevalence of obesity has plateaued in the past 2 to 3 years in industrialized countries including the US, but continues to rise in developing countries. Gender, ethnic, and regional differences complicate obesity epidemiology. The rate of increase is higher in women compared to men, and while rates of increase are similar across ethnicities, mean BMI is highest in Blacks, followed by Hispanics, then Caucasians. Data regarding the association between obesity and socioeconomic status are conflicting; evidence suggests an inverse correlation between low socioeconomic status and obesity in low- and middle-income countries but a positive correlation in industrialized countries. Obesity prevalence is increased in rural compared to urban environments in the United States, although this relationship is inverted in developing countries.

The disease burden associated with obesity is substantial. Multiple confounders complicate quantification of risk, not the least of which is variability in the degree of obesity itself, with increasing BMI being associated with increasing risk of mortality and disease in a dose-dependent but nonlinear fashion. Obesity is associated with decreased lifespan. Data from the Framingham Heart Study demonstrate a loss of 3 and 6 years of life for overweight and obese men respectively,⁸ while NHANES data demonstrate a loss of 13 years of life for severely obese men (BMI >45).⁹ Overweight and obesity are associated with an increased risk of multiple diseases, among which type II diabetes is particularly important. The association between obesity and diabetes is robust; relative risks for diabetes range from 2 to 15 for BMI in the overweight range and 20 to 90 for BMI in the obese range. The CDC estimates that in the United States in 2011, the prevalence of type II diabetes was 8.3% among all adults and 27% among those over 65 years of age. Furthermore, 35% of all US adults, and 50% of US adults over 65 years of age have elevated fasting blood glucose or HbA1c consistent with prediabetes. If current trends persist, the prevalence of diabetes in the United States in 2050 will exceed 30%, and worldwide trends parallel these US data.

Obesity is associated with an increased risk of multiple diseases, including atherosclerosis, hypertension, hyperlipidemia, hepatic steatosis and steatohepatitis, sleep apnea, osteoarthritis, gallbladder disease, endocrine disorders, autoimmune disease, allergy and atopy, multiple types of cancer, and depression. Metabolic disease encompasses all of physiology. Risk ratios for overweight and obesity-related diseases vary substantially depending on BMI, ranging from 2 to 5 for stage I obesity with dramatic dose-dependent increases in risk with increasing BMI. For example, the prevalence of hepatic steatosis in the general population is generally estimated to be approximately 30%, increases progressively with increasing BMI, and exceeds 90% in obese patients with BMI >40. In the NHANES population, the prevalence of sleep apnea was 3% in nonobese men and 12% in obese men (BMI >30),¹⁰ but in a separate study of patients with severe obesity (BMI >40), prevalence exceeded 70%.¹¹ This disease burden is associated with significant economic costs. While accurate quantification of obesity-related healthcare costs is challenging and complicated by regional variability in payer systems and patient demographics, a recent systematic review estimated that costs directly attributable to overweight and obesity in the United States exceed 100 billion dollars annually and constitute 5% to 10% of total US healthcare spending.

MEDICAL MANAGEMENT

Treatment Strategies

The medical management of obesity falls into two primary categories: lifestyle intervention and pharmacotherapy. Both strategies, with rare exceptions, achieve similar results, with modest weight loss and high recidivism. Nonetheless, both strategies hold significant untapped promise, with advances expected in coming decades, particularly in the areas of environmental engineering and pharmacotherapy.

Lifestyle Interventions

3 Lifestyle interventions for obesity include any or all of three basic components: diet modification, exercise, and psychological therapy. Interventions may be unsupervised or administered under the supervision of clinicians, dietitians, or commercial weight loss plans, and may be individualized or administered in group programs.

Diet modification is the mainstay of lifestyle intervention. Diet strategies vary with respect to macronutrient composition, daily caloric intake, and food and caloric measurement methods, and include low-carbohydrate diets, low-fat diets, meal replacement strategies, Mediterranean diets, very low-calorie diets, and multiple commercial diet plans. No clear evidence demonstrates advantages of any specific diet plan over others. Specifically, macronutrient composition does not impact on weight loss when caloric intake is controlled – total calories, rather than the macronutrient composition of those calories, is the variable that determines weight loss. In contrast to weight loss, conflicting evidence exists regarding the role of macronutrient composition in improvement of metabolic disease, with some evidence suggesting that low-carbohydrate diets (which include low-glycemic index–high-fiber diets and very low-carbohydrate diets), when compared to low-fat diets, may be associated with greater improvements in insulin resistance and triglyceride levels, and higher resting energy expenditure. These studies must be interpreted with caution as follow-up is relatively short, and low-

carbohydrate diets may be associated with adverse changes in low-density lipoprotein levels.¹² Low-carbohydrate diets also appear to provide better compliance than other diet strategies over short-term follow-up of less than 6 months, but compliance differences vanish at follow-up exceeding 1 year.

Physical activity is a central component of lifestyle intervention for obesity. Exercise alone achieves only modest weight loss, but exercise and diet potentiate each other. Importantly, exercise reduces obesity-related mortality and cardiovascular disease risk independent of weight loss. Data regarding the optimal type, duration, frequency, and intensity of exercise are conflicting and specific evidence-based guidelines remain elusive. High intensity exercise may be more effective for weight loss, but many obese patients are unable to engage in even moderate intensity exercise due to comorbid diseases such as osteoarthritis. Increased daily nonexercise activities such as walking and stair use nonetheless may provide modest weight loss and cardiovascular health benefits.

Of the wide range of psychological techniques used to treat obesity, cognitive-behavioral therapy is most common. Cognitive-behavioral therapy achieves modest weight loss in the obese of approximately 2 to 3 kg at 1-year follow-up, with increased weight loss when combined with diet and/or exercise. Increased frequency of psychological intervention and group therapy compared with individual therapy are associated with greater weight loss.

Intensive lifestyle interventions are supervised multicomponent plans that involve a combination of diet, exercise, and behavioral modification, with periodic monitoring by coaches and dietitians, and individual or group psychological counseling. Two NIH-sponsored randomized controlled trials suggest that intensive lifestyle interventions provide more durable results than standard lifestyle interventions, although long-term outcomes of metabolic disease are conflicting. The Diabetes Prevention Program randomized 3,234 overweight or obese insulin-resistant patients (mean BMI 34) to 1 of 3 experimental arms: intensive lifestyle interventions, metformin treatment, or placebo treatment.¹³ After a mean follow-up of 2.8 years, average weight loss in the intensive lifestyle interventions group was 5.6 kg compared with 2.1 kg and 0.1 kg for the metformin and placebo groups respectively; at 10 years an average weight loss of 2 kg was maintained in both intensive lifestyle interventions and metformin arms relative to the placebo arm. The cumulative risk of incident diabetes was 34% lower in the intensive lifestyle interventions arm and 18% lower in the metformin arm relative to the placebo arm. The NIH-sponsored Look AHEAD (Action for Health in Diabetes) study randomized 5,145 overweight or obese diabetic patients to a 4-year intensive lifestyle intervention involving diet and exercise modification with regular on-site visits and counseling, or standard primary care provider-supervised diabetes and weight loss education. After 8 years, mean weight loss was 4.7% and 2.1% in the intensive lifestyle intervention and standard care arms respectively.¹⁴ Nonetheless, the study was halted after 11 years after no difference in cardiovascular events was observed. These studies demonstrate that while modest, weight loss may be maintained over long periods with intensive lifestyle interventions, although the effects on metabolic disease are equivocal. Of importance, in Look AHEAD, a subset of patients in each arm (27% and 17% in intensive lifestyle intervention and standard care arms, respectively), maintained a loss of >10% of total starting weight, suggesting that subpopulations of patients are more responsive than others to lifestyle interventions, and that identification of predictors of responsiveness would permit better allocation of care.

Assessing the overall efficacy of lifestyle interventions for obesity is challenging, as results vary depending on the subgroup studied, follow-up is variable and often short, and program and outcome reporting methods are widely disparate. The resultant complex body of literature limits our current understanding of the efficacy of such interventions. Nonetheless, a preponderance of data suggests that results of lifestyle interventions for obesity are modest, with mean weight loss between 2% and 10% of total body weight over follow-up periods from 6 to 48 months. Unsupervised individual efforts underperform more intensive, multicomponent, supervised, group interventions. Compliance is a critical issue; individual diet programs are associated with attrition that may exceed 90% over a year or more while attrition for intensive supervised efforts is less. Weight regain after program discontinuation is common and long-term adherence to lifestyle changes is low. Despite these limitations, modest weight loss, or exercise in the absence of weight loss, appears to have measurable if modest beneficial effects on metabolic disease, with a subset of patients being responsive to such interventions. As such, lifestyle interventions should be a component of the treatment of all obese patients, but only rarely achieve dramatic and durable results.

Environmental Interventions – The Future

An understanding of importance of the interaction between environment and human genetics in the

pathogenesis of obesity has shifted focus away from individual patient behavior modification and toward manipulation of the *obesogenic built environment*. While rigorous data and proof of causality are emerging, specific characteristics of the built environment have been linked to obesity, including proximity and prevalence of fast food restaurants and full-service grocery stores, access to and quality of exercise facilities, parks, and sidewalks, school and work environment food and exercise resources, and public transit infrastructure. An emerging field of environmental and social engineering will shift the focus of lifestyle intervention from individual to environment, and holds promise as next-generation treatment for obesity.

Pharmacotherapy

4 The history of pharmacotherapy for obesity is replete with drugs that have been introduced with much enthusiasm and variable efficacy but subsequently withdrawn due to unacceptable and in many cases life-threatening side effects that became apparent only after widespread use. Sheep thyroid extract was used in the late 19th century, while in the early 20th century, workers in the dye industry exposed to 2, 4-dinitrophenol were observed to lose weight, leading to its use as a weight loss drug in the 1930s. Amphetamines were popular weight loss drugs in the 1950–60s. All these agents were abandoned due to prohibitive side effects. The modest efficacy of weight loss drugs is testament to the multiple redundant physiologic systems that act to defend adipose tissue stores in the face of interventions designed to reduce those stores. The frequent adverse effects of weight loss drugs speak to the interface between body weight regulation and multiple fundamental physiologic processes, manipulation of which entails substantial risk.

The largest and most important class of weight loss drugs targets monoamine signaling mediators (norepinephrine, serotonin, dopamine, histamine) involved in CNS/hypothalamic control of satiety and hunger. Many of these agents regulate multiple pathways and demonstrate overlapping activities. Sympathomimetic agents that primarily potentiate norepinephrine release include phentermine, introduced in 1959 and still in use today, and phenylpropanolamine, used as a decongestant and also as a weight loss drug since the 1970s, but withdrawn from the market in 2000 after being associated with an increased risk of stroke. Drugs that primarily potentiate serotonin activity include fenfluramine, introduced in 1973 and withdrawn from the market in 1997, sibutramine (Meridia), a serotonin, norepinephrine, and dopamine reuptake inhibitor with primary effects on serotonin and norepinephrine, introduced in 1997 but withdrawn in 2010 after being linked to increased risks of myocardial infarction and stroke, and lorcaserin (Belviq), a selective serotonin 2C agonist approved by the FDA in 2012. Drugs that target dopamine signaling are currently being studied in clinical trials (e.g., bupropion, tesofensine). Targeting multiple monoamine signaling pathways provides synergy. The combination drug fenfluramine/phentermine (“Fen-phen”), introduced in 1992, demonstrated increased efficacy over either agent alone, but was withdrawn from the market in 1997 after widespread use revealed serious morbidity attributable to fenfluramine, including pulmonary hypertension and cardiac valvular disease. In 2013, the FDA approved a combination drug of phentermine and topiramate, an antiepileptic with multiple CNS activities (Qsymia). A combination formulation of bupropion and naltrexone, an opioid antagonist which stimulates pro-opiomelanocortin neurons, is currently being studied in research trials.

Gut peptides have diverse metabolic functions including regulating satiety and hunger within the hypothalamic feeding center, and include glucagon-like peptide 1 (GLP-1), cholecystikinin, ghrelin, oxyntomodulin, pancreatic polypeptide, and amylin. Drugs based on these mediators show promise. Many gut peptides have short biologic half-lives and research has focused on long-acting analogs or mediators that target degradation pathways. GLP-1, secreted by ileal L cells in response to a meal, induces satiety and potentiates insulin secretion and peripheral insulin sensitivity. Long-acting GLP-1 analogs, including liraglutide (Victoza) and exenatide (Byetta) are FDA approved for treatment of type 2 diabetes and are under investigation as primary weight loss agents.¹⁵ Ghrelin is so far the only known orexigenic hormone, and ghrelin antagonists, agonists of ghrelin degradation pathways, and antighrelin vaccines are in development. Amylin, released by pancreatic beta cells, induces satiety via CNS-based mechanisms and also potentiates peripheral insulin resistance; pramlintide (Symlin), a human amylin agonist, is approved for treatment of diabetes and induces modest weight loss. Orlistat (Xenical), approved by FDA in 1999, is a pancreatic lipase inhibitor that blocks intestinal absorption of fat, and the only drug to date that functions by reducing absorption of ingested calories. Side effects of orlistat include diarrhea, steatorrhea, and increased risks of kidney stones and pancreatitis. Second-generation lipase inhibitors are in development.

Agents designed to manipulate neuropeptide signaling within the hypothalamus, while not yet

approved for use in humans, are important targets, and include drugs directed toward leptin, melanocortin-4 receptor (MC4R), neuropeptide Y, and melanin-concentrating hormone. While leptin resistance has confounded development of leptin as a therapeutic agent, recent data from animal models suggest that concomitant treatment of endoplasmic reticulum stress may abrogate leptin resistance,¹⁶ while separate research demonstrates that amylin agonists also restore leptin sensitivity.¹⁷ These lines of research have reinvigorated interest in leptin therapy. Mutations in the MC4R gene, a central hypothalamic satiety mediator, are implicated in up to 5% of cases of common human obesity, and MC4R agonists are currently in development. Other central-acting agents are directed toward endocannabinoid signaling: rimonabant (Acomplia), a selective endocannabinoid antagonist, was denied FDA approval in 2008 despite promising weight loss results in clinical trials due to an association with depression and suicide, but interest in manipulation of endocannabinoid signaling persists.

Manipulation of thermogenesis and metabolic rate remains an active field of research. Thyroid hormone achieves weight loss by increasing metabolic rate, but is associated with cardiac toxicity and has detrimental effects on glucose homeostasis. Despite these failures, research persists. Many agents discussed above that regulate food intake, most notably the sympathomimetics, also increase metabolic rate, and it is unclear to what extent these effects contribute to weight loss. Agents that regulate steroid metabolism, fatty acid oxidation and other aspects of adipose tissue, and skeletal muscle metabolism are under study. Dietary constituents also regulate thermogenesis, including methylxanthines (e.g., caffeine), polyphenols (e.g., resveratrol, quercetin), capsaicinoids (found in chili peppers and mustards), and medium-chain fatty acids, all of which represent potential therapeutic agents.

Overall efficacy of current obesity pharmacotherapy is modest, achieving weight loss of 3% to 10% of total body weight. Most agents demonstrate synergy with lifestyle interventions. Current drugs approved by the FDA specifically for weight loss include orlistat, the only drug approved for long-term use; phentermine, approved for short-term use (<12 weeks) due to addiction potential and cardiovascular toxicity; lorcaserin, FDA approved for use as an adjunct to lifestyle interventions; and phentermine/topiramate. The XENDOS study (XENical in the Prevention of Diabetes in Obese Subjects) randomized 3,305 patients to lifestyle intervention combined with either orlistat or placebo and at 4 years, and demonstrated a 5.8-kg weight loss in the orlistat arm compared with a 3.0-kg weight loss in the placebo arm, as well as a reduced incidence of diabetes with orlistat therapy.¹⁸ Lorcaserin induced 5% weight loss compared with 3% in placebo-treated patients at 1 year.¹⁹ The phentermine/topiramate combination drug achieved 10.5% weight loss compared with 1.8% in placebo-treated patients at 2-year follow-up.²⁰

A complete summary of obesity pharmacotherapy is beyond the scope of this chapter, which has by necessity omitted important areas of research, including drugs that target steroid metabolism, lipid metabolism, adipocyte differentiation and proliferation, and efforts to shift white adipose tissue toward a brown adipose tissue phenotype (the “browning” of adipose tissue). This discussion has focused on agents designed to treat obesity directly with the goal of weight loss, but an important parallel class of drugs target metabolic disease independent of or in conjunction with weight loss. The activities of weight loss drugs are complex and overlapping, with many agents regulating body weight and metabolism via multiple mechanisms. Multiple redundancies in the regulation of energy homeostasis suggest that drug combinations will enhance efficacy. As an understanding of these mechanisms increases, safe and effective pharmacotherapy for obesity and metabolic disease will emerge.

SURGICAL MANAGEMENT

Bariatric Surgery – Beginnings

5 In contrast to lifestyle interventions and pharmacotherapy, surgical management of obesity is highly efficacious. Modern bariatric surgery (Gr. *baros*, heavy, burden) is the result of over a half-century of evolution in surgical technique that has its genesis in the 1940–50s with experiments in animals and isolated operations in humans that employed small intestinal resection and jejunoileal and ileocolic bypasses of various anatomic configurations. These operations involved substantial morbidity and did not achieve widespread acceptance, but set the stage for development of the *jejunoileal bypass*, the first bariatric operation to be widely applied in humans. Jejunoileal bypass involved division of the jejunum 14 inches distal to the ligament of Treitz and creation of a jejunoileostomy 4 inches proximal to the ileocecal valve, and was thus referred to as a “14–4 bypass” (Fig. 46-1). In 1969, Payne and Dewind²¹ published the first report describing long-term clinical outcomes in a large group of patients who

underwent jejunioleal bypass in the 1950–60s, describing dramatic weight loss (“A total of 10,373 pounds have been lost by the (80) patients”) along with improvements in insulin resistance, hypercholesterolemia, and hepatic steatosis. Jejunioleal bypass was widely used throughout the 1960s and early 1970s.

Despite its efficacy, as experience accumulated, it became clear that jejunioleal bypass was associated with significant morbidity. Diarrhea, steatorrhea, dehydration, electrolyte imbalances, and micro- and macronutrient deficiencies resulted from the highly malabsorptive nature of the operation. Patients also suffered a host of complications not obviously linked to malabsorption, including liver disease, nephropathy, arthropathy, neuropathy, and myopathy. While the cause of these latter complications was not completely clear, an immune response directed toward bacterial overgrowth in the blind intestinal limb was implicated. Overall morbidity afflicted as many as 70% of patients and led to abandonment of jejunioleal bypass by the late 1970s. Nonetheless, up to 30% of patients achieved good results, and the clinician may still encounter rare remaining patients. Indications for reversal or conversion to modern bariatric operations are not well established and must be considered on an individual basis, but include progressive liver or kidney disease not attributable to other causes. Some clinicians advocate reversal and conversion to a modern bariatric operation in all patients who are good operative candidates regardless of the presence or absence of complications.

Figure 46-1. Jejunioleal bypass. The jejunum is divided 14 in distal to the ligament of Treitz, and a jejunioleostomy is created 4 in proximal to the ileocecal valve. Note that the defunctionalized jejunioleal limb is out of continuity with biliopancreatic effluent, predisposing to limb stasis.

Gastric Bypass – The Gold Standard

With the decline of jejunioleal bypass, surgeons began searching for alternatives. In the 1960s, Edward Mason at the University of Iowa experimented with operations based on observations that patients who underwent gastric resections for ulcer disease had difficulty maintaining their weight. Mason’s efforts led to the development of the *gastric bypass*, for which he earned the title “father of bariatric surgery.” Mason’s original gastric bypass consisted of a pouch gastropasty with a loop gastrojejunostomy reconstruction. Gastric bypass subsequently evolved through a number of iterations, all with important clinical implications. Large horizontal fundal-based pouches were replaced with smaller vertical lesser curve-based pouches, which improve gastric emptying. Undivided gastric pouches were associated with high rates of staple-line dehiscence and gastrogastic fistula, and were replaced with divided gastric bypass, expedited by the development of cutting staplers. Roux-en-Y reconstruction, compared to loop reconstruction, reduces tension on the gastrojejunal anastomosis and prevents bile reflux gastritis, but may be associated with higher rates of anastomotic ulcer disease. Retrocolic Roux limbs may improve pouch emptying and generate less tension on the gastrojejunostomy, but at the price of higher rates of mesocolic internal hernias. Banding of the gastrojejunal anastomosis may increase weight loss, but also increases risks of stenosis, obstruction, and erosion. Variations persist, including retrocolic Roux limbs, loop reconstructions (“minigastric bypass”), and prosthetic-banded gastric pouches. The modern gastric bypass practiced by the majority of surgeons today consists of a divided, unbanded, lesser curve-based pouch gastropasty of 15 to 30 cc with an antecolic Roux-en-Y gastrojejunal reconstruction with a 100-cm Roux/alimentary limb and a 50- to 100-cm afferent/biliopancreatic limb (Fig. 46-2). The modern gastric bypass is a robust operation because within limits, subtle variations in technique, including pouch size and morphology and intestinal limb length and position, do not greatly affect efficacy or morbidity. Gastric bypass remains, as of this writing, the dominant bariatric operation worldwide and the gold standard against which all other operations are measured.

Figure 46-2. Anatomy of modern Roux-en-Y gastric bypass. Modern gastric bypass consists of a divided pouch gastropasty with Roux-en-Y jejunojunal reconstruction. The Roux limb is most commonly placed in the antecolic position. Intestinal limbs are termed with either standard Roux (Roux, afferent, efferent) or bariatric (alimentary, biliopancreatic, common channel) nomenclature as shown.

Malabsorption Revisited

Despite the failure of jejunioileal bypass, interest in operations that relied on small intestine bypass persisted. *Biliopancreatic diversion* consists of an antrectomy with a gastrojejunostomy and distal Roux-en-Y jejunioileostomy. The *duodenal switch modification of the biliopancreatic diversion* involves a sleeve gastrectomy, division of the duodenum distal to the pylorus, and a duodenojejunostomy and distal Roux-en-Y jejunioileostomy, thus maintaining the pylorus in the alimentary stream (Fig. 46-3). Biliopancreatic diversion/duodenal switch differs from jejunioileal bypass in two important regards. First, maintenance of forward flow of biliopancreatic effluent in the bypassed afferent limb prevents stasis and bacterial overgrowth. Second, common channel length was increased to 100 cm, reducing malabsorptive complications. Biliopancreatic diversion/duodenal switch provides weight loss and metabolic disease remission equivalent to, and in many series, greater than gastric bypass. Morbidity and mortality for biliopancreatic diversion/duodenal switch span a wide range, with centers with significant expertise reporting low rates similar to gastric bypass. Nonetheless, when the literature as a whole is considered, biliopancreatic diversion/duodenal switch is associated with higher morbidity and mortality than gastric bypass. Perioperative mortality reported by meta-analyses is at least twofold higher than gastric bypass, possibly due to a higher risk of anastomotic dehiscence, as laparoscopic creation of the duodenojejunal anastomosis associated with the duodenal switch modification is technically challenging.²² Late malabsorptive complications which may require surgical revision, while much improved over jejunioileal bypass, range from 2% to 20%. Unlike gastric bypass, in which small changes in pouch size or limb length do not substantially alter clinical outcome, outcomes of biliopancreatic diversion/duodenal switch are relatively sensitive to differences in efferent limb length, small changes in which may make the difference between poor weight loss and malabsorptive complications. Predicting the correct efferent limb length for an individual patient is challenging. Most surgeons advocate a fixed length of 100 cm, while others advocate an *ad hoc* limb length proportional to total small intestine length. While advocated by select surgeons and associated with good outcomes in centers with significant experience, biliopancreatic diversion/duodenal switch is nonetheless waning in use, currently comprising less than 2% of bariatric operations.

Figure 46-3. Biliopancreatic diversion (BPD). BPD involves a distal antrectomy with a Roux-en-Y jejunoileal reconstruction; BPD + DS involves a sleeve gastrectomy with a Roux-en-Y duodenal reconstruction, with the duodenoileostomy created 2 cm distal to the pylorus, thus preserving the pyloric emptying mechanism. Note that, unlike JIBP, the afferent/biliopancreatic jejunoileal limb is in continuity with biliopancreatic effluent, reducing limb stasis.

Pure Restriction

In Mason's era, morbidity from gastric bypass was not trivial. In an effort to design a simpler and safer operation, Mason experimented with gastroplasties that precluded the need for small intestinal reconstruction. Like gastric bypass, these operations evolved through a number of iterations, eventually leading to the modern *vertical banded gastroplasty*, which involves creation of a partitioned upper stomach pouch with a prosthetic band restricting pouch outlet diameter (Fig. 46-4). Vertical banded gastroplasty achieved widespread acceptance and peaked in the 1970–80s. Vertical banded gastroplasty weight loss is substantially less and late weight regain substantially greater compared to gastric bypass, however, and vertical banded gastroplasty has therefore been relegated to a minority operation that is rapidly being eliminated from use.

Study of prosthetic bands applied to the upper stomach to limit food intake began in the late 1970s using devices made from prolene, marlex, and other materials. These devices were nonadjustable and plagued with complications related to erosion, migration, stenosis, and obstruction. Efforts persisted, eventually culminating in the modern *adjustable gastric band*, a silicone device that was FDA approved in the United States in 2001 (Fig. 46-5). A primary advantage of gastric band is its technical simplicity and low rates of major morbidity and mortality. Unlike gastric bypass, which continues to be associated with low but finite rates of anastomotic dehiscence and mortality, gastric band is associated with 5 to 10 lower rates of life-threatening complications and mortality. Much enthusiasm accompanied the introduction of gastric band in the late 1990s, but over the past decade, enthusiasm has waned for two reasons. First, therapeutic efficacy of gastric band in the majority of patients is substantially less than gastric bypass. Second, as years passed, late complication rates have increased. These complications, including band slippage, erosion, and esophageal dilation and development of gastroesophageal reflux disease (GERD), are usually not life-threatening, but range between 10% and 50% and often lead to band removal.²³ Despite these problems, gastric band efficacy, while not as high as gastric bypass, is acceptable. Gastric band remains the bariatric operation with the lowest major morbidity and mortality rates, an appealing quality for risk-averse patients. Gastric band does not require Roux-en-Y reconstruction, an advantage in patients with complex abdominal surgical histories. For these reasons, gastric band remains an important component of the bariatric surgery repertoire.

Figure 46-4. Vertical banded gastroplasty. A partitioned proximal gastric pouch is created with a linear stapler, and outflow limited with a prosthetic band. Variations included a divided staple line and different materials used for banding.

Figure 46-5. Gastric band. A silicone adjustable band is positioned around the upper stomach, creating a gastric pouch. A port attached to the band via silicone tubing is placed in the subcutaneous tissue in the abdominal wall, permitting percutaneous access and adjustment of band diameter.

Sleeve gastrectomy was introduced initially as a component of the duodenal switch modification of biliopancreatic diversion, but did not gain significant attention as a stand-alone bariatric operation until the early 2000s. Sleeve gastrectomy involves a lateral gastrectomy, leaving a narrow “sleeve” of stomach 32 to 40 Fr in diameter (Fig. 46-6). Originally proposed as the first step in a staged approach for high BMI patients prior to definitive gastric bypass, early follow-up data demonstrated excellent results, and long-term efficacy appears similar to gastric bypass. Sleeve gastrectomy is associated with perioperative complication rates similar to gastric bypass, but late complications are rare, in part due to elimination of morbidity associated with alterations in small intestinal anatomy. For these reasons, sleeve gastrectomy has engendered significant enthusiasm and is rapidly increasing in utilization.

Figure 46-6. Sleeve gastrectomy. A lateral gastrectomy is performed with a linear cutting stapler, creating narrow gastric reservoir 32 to 40 Fr in diameter.

Modern Bariatric Surgery

6 Bariatric operations in addition to those described above exist, including variants of gastric bypass, biliopancreatic diversion/duodenal switch, and vertical banded gastroplasty as well as distinct alternative operations. Currently gastric bypass, sleeve gastrectomy, and gastric band are the mainstays,

while biliopancreatic diversion/duodenal switch comprises a waning minority. Worldwide utilization rates in 2011 were gastric bypass 47%, sleeve gastrectomy 28%, gastric band 18%, and biliopancreatic diversion/duodenal switch 2% of all bariatric operations, with a marked increase in sleeve gastrectomy and decrease in gastric band in recent years.²⁴ The introduction of laparoscopy in the early 1990s provided significant advantages for many surgical patients but perhaps none more so than the obese. Wound infections and ventral hernias afflicted 30% to 90% of patients undergoing bariatric surgery via laparotomy, complications that were virtually eliminated with laparoscopy. Surgeons began exploring laparoscopic gastric bypass in the mid-1990s, but laparoscopy came with a price, introducing technical challenges dissimilar from open bariatric surgery, with a long, arduous learning curve that may exceed 100 cases for laparoscopic gastric bypass. These challenges engendered a response that included fellowship training programs and programmatic efforts to codify technique and care, including certification of bariatric surgery centers by surgical societies. These efforts, along with increasing surgeon experience, have reduced current morbidity and mortality to levels substantially lower than in the prelaparoscopic era. Currently, a laparoscopic approach is considered standard of care for bariatric surgery patients in the absence of a prohibitive prior surgical history.

Efficacy

Bariatric surgery achieves dramatic results. Weight loss is commonly reported as a percent age of *excess weight lost* (EWL), defined as the difference between presurgical weight and ideal weight, with ideal weight calculated for BMI = 25 for height. Weight loss typically peaks 1 to 2 years after surgery and may approach 80% to 90% EWL, followed by partial weight regain 3 to 10 years after surgery, leading to a plateau at 50% to 70% EWL at long-term follow-up.²⁵ The mechanisms underlying this weight loss pattern are unknown but may involve development of adaptive eating patterns that increase caloric intake over time. For gastric band, weight loss is typically slower and more gradual, with a plateau after 2 to 3 years. These varying patterns of weight loss complicate comparison of results of different operations and analysis of published data due to variable length of follow-up among studies. Analysis is further complicated by significant attrition of patients over long-term follow-up in most studies. Despite these challenges, meta-analyses, controlled trials, and uncontrolled case series provide estimates of the efficacy of bariatric operations (Table 46-1). Weight loss is highest for biliopancreatic diversion/duodenal switch, ranging from 55% to 75% EWL, followed by gastric bypass and sleeve gastrectomy (50% to 70% EWL) and gastric band (40% to 60% EWL).

Rates of improvement and remission of metabolic diseases parallel weight loss, with gastric bypass, sleeve gastrectomy, and biliopancreatic diversion/duodenal switch associated with higher remission rates than gastric band. Diabetes, steatosis, sleep apnea, hypertension, and hyperlipidemia improvement/remission rates range from 60% to over 90% (Table 46-2). Weight loss is durable, lasting decades in most patients, and accompanied by marked reductions in long-term incident diabetes, cardiovascular disease, and cancer, increased quality of life, reduced long-term healthcare costs, and a 25% to 40% reduction in long-term mortality. Randomized controlled trials demonstrate that bariatric surgery is substantially more efficacious than medical therapy for weight loss and diabetes, and multiple medical societies, including the American Diabetes Association, the International Diabetes Federation, and the American Heart Association, endorse bariatric surgery as treatment for metabolic disease.

Despite its efficacy, results of bariatric surgery are variable, with a substantial minority of patients achieving significantly better than average weight loss and disease response rates, while a similar minority experience suboptimal results. Anywhere from 10% to 30% of patients achieve <50% EWL, which may be due to failure to lose weight initially, or weight regain after a period of adequate weight loss. Mechanisms underlying such failures are poorly defined, and identification of accurate predictors of response to surgery is an important area of research. While suboptimal results are often attributed to lack of patient compliance with postoperative diet and exercise, these arguments ring false, echoing similar arguments that attribute obesity itself to a lack of “willpower.” Instead, compelling evidence implicates genetic and epigenetic mechanisms. Like obesity itself, responses to bariatric surgery are highly heritable. Ethnicity is a predictor of outcome, with Caucasians and Hispanics experiencing greater weight loss than Blacks and Asians. Multiple single-nucleotide polymorphisms have been linked to surgical outcome. Future research will identify clinical and genetic predictors of response and permit optimization of allocation of surgical resources.

Perioperative Mortality and Morbidity

Morbidity and mortality associated with bariatric surgery have decreased over the past two decades as surgeon experience increased and techniques evolved. Currently, gastric bypass and gastric band are associated with mortality risks similar to hip replacement and laparoscopic cholecystectomy, respectively. Perioperative mortality is highest for biliopancreatic diversion/duodenal switch, followed by gastric bypass and sleeve gastrectomy, then gastric band (Table 46-3). Life-threatening perioperative morbidity associated with gastric bypass and sleeve gastrectomy consists primarily of anastomotic dehiscence, staple-line leaks, hemorrhage, thromboembolic events, and cardiac events. Life-threatening perioperative morbidity associated with gastric band is rare and consists primarily of gastric perforation, thromboembolic events, and cardiac events.

The most dire perioperative complication of gastric bypass is anastomotic dehiscence of the gastrojejunostomy which usually occurs within 2 weeks of surgery. Incidences in most series range from 0.1% to 4%, although recent data suggest that anastomotic dehiscence rates are decreasing and high-volume centers report rates in the range of 0.1% to 0.2%. Signs and symptoms are similar to those of anastomotic dehiscence after any intestinal operation, but may be less apparent in the obese. Persistent tachycardia and abdominal pain are important but nonspecific sentinel signs. Upper GI radiographs may be of diagnostic utility but lack sensitivity. Abdominal CT scan, even within a few days of surgery, may be useful, as the lack of a fluid collection near the gastrojejunostomy has a high negative predictive value for leak, while contrast extravasation has a high positive predictive value. Nonetheless, data are conflicting regarding the sensitivity and specificity of radiologic studies for diagnosing anastomotic dehiscence, and laparoscopic reexploration should be employed aggressively in suspected cases. Operative management consists of washout, wide drainage, judicious attempt at repair, and distal enteral access, usually with a gastrostomy tube in the remnant stomach, although a jejunostomy tube in the distal Roux limb or biliary limb is an option if access to the remnant stomach is difficult. Anastomotic dehiscence can be managed laparoscopically in some cases, reducing the high risk of ventral hernia associated with laparotomy. Most will heal if sepsis is controlled.

Staple-line leaks are an equally dire event after sleeve gastrectomy, occurring anywhere from 1–2 weeks to many months after surgery. Leaks may occur at any point along the staple line, but when involving the thicker tissue of the antrum may be less prone to heal, and interval conversion to gastric bypass with resection of the involved portion of gastric sleeve may be necessary. Proper stapler selection and use during primary operation with avoidance of overly narrow sleeves (current consensus recommends 32- to 40-Fr diameter) reduce the risk of sleeve gastrectomy staple-line leaks, which currently occur with an incidence of approximately 1% to 3%. Gastric band is only rarely associated with perioperative septic complications, most often in the form of gastric perforation, which occurs in 0% to 0.5% of cases. Perforation, if not recognized, may be life-threatening and is a primary cause of rare perioperative mortality and major morbidity after gastric band.

GBP, gastric bypass; SG, sleeve gastrectomy; GB, gastric band; BPD, biliopancreatic diversion; NR, not reported.

Perioperative hemorrhage after gastric bypass occurs with an incidence of 1% to 4%, often originates from staple lines, and may be intraperitoneal or intraluminal. Intraluminal bleeding presents with melena and is often self-limited, requiring only transfusion and observation. Infrequently, endoscopic or operative intervention may be necessary. Hemorrhage after sleeve gastrectomy ranges from 1% to 4%, is usually intraperitoneal from the gastric staple line, and may require operative intervention, although observation in the hemodynamically stable patient is a reasonable initial course. Early small bowel obstruction, and thromboembolic, pulmonary, and cardiac events comprise the majority of the remainder of acute postoperative complications after bariatric surgery. Pathophysiology is not substantially different than after nonbariatric GI operations, although the obese may be at higher risk, reinforcing the importance of preoperative evaluation and preparation.

Late Morbidity

Late morbidity after bariatric surgery is similar to that associated with complex nonbariatric GI operations, may occur months or years later, and often presents with abdominal pain. Gallbladder disease and small bowel obstruction from adhesions and ventral/trocar hernias may occur after all bariatric operations. Other complications are operation specific. While definitions vary, overall late morbidity rates for gastric bypass range from 5% to 10%. Many late complications of gastric bypass result from Roux-en-Y anatomy. Internal hernias occur in 0.5% to 9% of patients, and are categorized as mesenteric (common to all Roux-en-Y reconstructions, in which bowel passes through the mesenteric split in the Roux limb), mesocolic (specific to retrocolic reconstructions, in which bowel passes through the mesocolic defect created for the Roux limb), and Petersen's (more often associated with antecolic than retrocolic reconstructions, in which bowel passes under the Roux limb and its mesentery) (Fig. 46-7).²⁶ Although closure of internal hernia defects at primary operation is straightforward and recommended, long-term clinical follow-up data do not demonstrate that this practice reduces hernia rates compared with series in which routine closure was not performed, possibly because of lack of scar tissue formation at the sites of closure, and/or loss of mesenteric adipose tissue with weight loss leading to late patency of previously closed defects. Patients often present years after surgery with a history of severe episodic abdominal pain. Diagnosis may be challenging, as obstipation may be absent and imaging normal even in the face of incarceration, especially if the biliopancreatic limb, which is out of continuity with the alimentary stream, is involved. A low threshold for operative exploration must be maintained in any patient with unrelenting abdominal pain after gastric bypass. Operative reduction and closure of internal hernia defects can usually be performed via a laparoscopic approach.

Figure 46-7. Internal hernias. Internal hernias may occur after any Roux-en-Y reconstruction, and include mesenteric, Petersen's, and mesocolic hernias. Weight loss after gastric bypass and loss of adipose tissue in the intestinal mesentery may predispose to internal herniation.

Gastrojejunal anastomotic ulcer occurs in 0.5% to 25% of patients after gastric bypass, with the majority of series reporting incidences between 2% and 8%. Tobacco or NSAID use increases risk, but ulcers may occur in the absence of these risk factors. Diagnosis by upper endoscopy is usually straightforward. Upper GI radiography is advisable to rule out an associated gastrogastic fistula, especially if an ulcer is recalcitrant to medical treatment or is associated with weight regain. Most ulcers heal with high-dose antacid therapy, and once healed, most surgeons recommend maintenance antacid therapy for life, although data supporting this practice are sparse. Rarely, ulcers recalcitrant to medical therapy require resection with anastomotic revision. Large pouches are a risk factor for ulcers due to retention of parietal cells in the distal gastric pouch that do not participate in negative inhibition of gastrin secretion, thus rationalizing pouch resection and anastomosis revision as a treatment strategy. Gastrogastic fistula occurs with an incidence of 0% to 2% and may be associated with ulcers. Gastrogastic fistula incidence has decreased substantially since the advent of divided gastric bypass. Gastrogastic fistula often results from incomplete division of the gastric pouch from the gastric remnant at primary operation. Stenosis of the gastrojejunostomy typically presents with intolerance of solid foods and vomiting within 1 to 3 months of surgery with a wide range of reported incidences from <1% to >20%, but most commonly 3% to 7%. Stenosis is usually easily treated with endoscopic dilation, although rare cases may require anastomotic revision. Retrograde intussusception at the jejunojejunostomy is a rare cause of abdominal pain after gastric bypass with a reported incidence of 0.1%. Pathogenesis is likely related to motility disorders resulting from disruption of enteroenteric nerves and divorce of the small intestine from duodenal pacemaker plexi with subsequent development of aberrant ectopic pacemakers in the involved intestinal limbs. Diagnosis may be challenging and imaging unreliable. Treatment consists of either plication/pexy of involved limbs or resection and revision of the jejunojejunostomy, with the latter approach associated with lower rates of recurrence.

The clinical presentation and differential diagnosis of abdominal pain after gastric bypass is diverse and diagnostic imaging may be unreliable. The clinician is not infrequently faced with a gastric bypass patient who presents with persistent pain in the absence of a clear cause after thorough diagnostic

evaluation. Exploratory laparoscopy in such patients provides a diagnosis in up to 90% of cases. Even in the absence of intraoperative findings other than patent internal hernia defects without incarceration, closure of defects provides relief in the majority of patients. Less commonly, in the absence of a clear cause, pain is presumed to result from atypical motility disorders associated with Roux-en-Y anatomy and may be difficult to treat ([Algorithm 46-1](#)).

Late complications after gastric band are common, afflicting 10% to 50% of patients, may occur years after primary operation, and include band slippage, band erosion, and development of GERD and esophageal motility disorders. Treatment often requires band explant, with late explant rates of 30% to 50% in some series. While long-term data are evolving, late complications after sleeve gastrectomy appear to be uncommon, with infrequent reports of sleeve stenosis (0.5% to 3%) and development of GERD.

Bariatric operations alter absorption of macro- and micronutrients. Protein and lipid malabsorption, steatorrhea, and protein wasting are rare after modern gastric bypass and virtually absent with gastric band and sleeve gastrectomy, but afflict anywhere from 2% to 20% of patients after biliopancreatic diversion/duodenal switch. The elimination of the pyloric emptying mechanism in gastric bypass is associated with dumping and hypoglycemic syndromes, the underlying mechanisms of which are not well understood. Early dumping occurs within 10 to 30 minutes of a meal, and is thought to result from intraluminal fluid shifts and acute intravascular volume depletion secondary to rapid emptying of hyperosmolar gastric contents into the small intestine. Early dumping is associated with tachycardia and diaphoresis. Aberrations in gut hormone secretion, including elevated secretion of vasoactive intestinal polypeptide, enteroglucagon, pancreatic polypeptide, and GLP-1, have been associated with a predisposition to early dumping. Late dumping occurs hours after a meal and is thought to be due to hypersecretion of insulin with subsequent reactive hypoglycemia; excess secretion of GLP-1 has also been implicated. Dumping and hypoglycemia typically respond to a low-carbohydrate diet and preprandial acarbose therapy. In cases recalcitrant to these measures, pharmacotherapy with agents that reduce insulin secretion, including octreotide, diazoxide, and calcium channel blockers, may be of benefit. Surgical banding of the gastric pouch to delay emptying has been employed with variable efficacy.

Micronutrient deficiencies are underreported after bariatric surgery. The reported prevalences of deficiencies of virtually all micronutrients after surgery span a broad range from 10% to >80% for biliopancreatic diversion/duodenal switch and gastric bypass. Deficiencies are less common after sleeve gastrectomy and gastric band. An understanding of the anatomic sites and mechanisms of micronutrient absorption affected by gastric bypass foregut diversion guides diagnosis and management. Anemia, neurologic, dermatologic, and GI symptoms are common clinical manifestations of many micronutrient deficiencies ([Table 46-4](#)). Acute deficiencies may involve dramatic presentations (e.g., thiamine deficiency and Wernicke encephalopathy). Chronic occult micronutrient deficiencies are associated with increased risk of chronic disease. Chronic magnesium deficiency, for example, is associated with an increased risk of type II diabetes. Chronic selenium deficiency has been associated with an increased risk of cancer and cardiovascular disease. The most common deficiencies associated with gastric bypass involve calcium, vitamin D, folate, iron, and B12. Vomiting due to stenosis or gastroenteritis increases the risks of severe micronutrient deficiencies, and nutritional status should be monitored carefully in any bariatric surgery patient with significant vomiting. It is important to note that obesity is associated with multiple micronutrient deficiencies independent of bariatric surgery, which should be identified and corrected in the preoperative period, and which may resurface in the postoperative period.

Patient Selection, Choice of Operation, Preoperative Preparation

Current criteria for candidacy for bariatric surgery are based on a 1991 NIH consensus conference, and include BMI ≥ 40 , or BMI ≥ 35 with at least one serious comorbidity of obesity. While widely used, these criteria are based on expert opinion rather than definitive epidemiologic data, and were established over two decades ago. Recent data suggest that bariatric surgery provides benefits to diabetic patients with BMI 30 to 34.9.²⁷ While consensus is evolving, the American Society for Metabolic and Bariatric Surgery (ASMBS) had issued a statement in support of bariatric surgery in this low BMI patient population, and the FDA, as the regulatory body that authorizes device use, approved gastric band for this subgroup in 2011. As data accrue, candidacy criteria will expand. Good outcomes have been reported in carefully selected patients with organ transplants, end-stage renal disease, compensated cirrhosis, HIV, and adolescents. Active uncontrolled cardiac, pulmonary, or psychiatric disease and uncompensated liver disease are generally considered absolute contraindications.

Algorithm 46-1

Algorithm 41-6. Algorithm for management of abdominal pain months or years after Roux-en-Y reconstruction.

The choice of bariatric operation is a complex decision. Gastric bypass is considered the gold-standard operation by many, although sleeve gastrectomy may soon supplant gastric bypass in this regard. The high failure rate of gastric band has led some to argue that it should be eliminated from the repertoire, although this is debated. While highly individualized, clinical considerations guide choice of operation. Gastric bypass is highly effective in ameliorating GERD; sleeve gastrectomy and gastric band, in contrast, may exacerbate GERD. Gastric bypass may provide theoretical advantages in the treatment of diabetes (discussed below), but sleeve gastrectomy and to a lesser extent gastric band are also highly efficacious in this regard. Gastric bypass is associated with increased intestinal oxalate absorption and hyperoxaluria, and sleeve gastrectomy or gastric band should therefore be considered in patients with a history of oxalate nephrolithiasis. Patients with severe gastroparesis may benefit from gastric bypass rather than sleeve gastrectomy or gastric band, although data in this subgroup are sparse, and gastric bypass itself may rarely lead to gastroparesis. Gastric band should be avoided in patients with dysphagia or esophageal motility disorders. Sleeve gastrectomy and gastric band avoid the need for manipulation of the small intestine and thus may be good choices in patients with complex abdominal surgical histories. Despite its high late morbidity and long-term failure rates, gastric band remains an option for risk-averse patients who are unaccepting of the relatively higher risk of perioperative morbidity and mortality associated with gastric bypass and sleeve gastrectomy.

Preoperative preparation includes thorough medical, psychological, and dietary evaluations. Patients should undergo age-appropriate cancer screening, and treatment for active medical issues should be optimized. Sleep apnea testing should be performed in most if not all patients, as the prevalence of sleep apnea in the obese population may exceed 70%, and appropriate treatment with continuous positive airway pressure (CPAP) should be instituted prior to surgery and continued through the perioperative period. Diabetes should be well controlled; while data do not support a specific value, a preoperative HbA1c <8 is a common target. Some degree of preoperative surgeon-supervised diet-induced weight loss should be achieved in most patients, as data suggest that this practice reduces hepatic steatosis, may reduce perioperative complications, and may be associated with improved long-term outcomes. Preoperative testing and treatment for *Helicobacter pylori* is recommended, although data suggesting that this practice decreases postoperative anastomotic ulcer risk is equivocal.

Operative Considerations

A thorough discussion of the technical aspects of bariatric surgery is beyond the scope of this chapter, but a few important issues warrant mention. Obesity is a risk factor for DVT, and aggressive DVT prophylaxis should be employed. Optimal prophylaxis agents and regimens have not been determined, but unfractionated or low-molecular-weight heparin during operation and continued through the hospitalization period is typical. Subtherapeutic dosing of these agents is common in the obese, and the American College of Chest Physicians recommends weight-based dosing.

Table 46-4 Select Micronutrient Deficiencies Associated with Bariatric Surgery

Micronutrient	Signs, Symptoms of Deficiency	Site of Absorption	Mechanism of Absorption, Other Issues
B9 (folate)	Macrocytic megaloblastic anemia, leukopenia, thrombocytopenia, glossitis, elevated homocysteine levels, neural tube defects in pregnancy	Duodenum, jejunum, ileum	Water soluble, conserved via enterohepatic circulation; B12 required for folate activation, B12 deficiency can cause folate deficiency; multivitamin generally sufficient for supplementation after surgery
B1 (thiamine)	Wernicke encephalopathy (ophthalmoplegia, nystagmus, ataxia, dementia), Korsakoff psychosis, beri-beri, peripheral neuropathy	Jejunum, ileum	Water soluble, depletion may occur with 2–3 weeks; rapid weight loss, vomiting increase risk of deficiency; symptoms of acute deficiency may mimic stroke
B6 (pyridoxine)	Seborrheic dermatitis, atrophic glossitis, conjunctivitis, neuropathy	Jejunum, ileum	Water soluble, passive absorption
B12 (cobalamin)	Macrocytic anemia, leukopenia, thrombocytopenia, glossitis, irreversible neuropathies	Ileum	Binds salivary R-proteins which prevent acid hydrolysis, then binds intrinsic factor secreted by parietal cells in gastric antrum; intrinsic factor-B12 complex absorbed in ileum; found in foods of animal origin – be alert for deficiency in vegetarians
C	Scurvy: malaise, myalgias, petechiae, mucosal bleeding, edema; iron deficiency	Jejunum	Symptomatic deficiency rare after bariatric surgery; potentiates iron absorption, should be used in iron deficient patients
D	Fatigue, myalgia, arthralgia, osteopenia	Jejunum, ileum	Fat soluble; deficiency common in obesity independent of surgery in up to 50% of patients
A	Xerophthalmia, night blindness, keratitis	Duodenum, jejunum, ileum	Fat soluble; deficiency associated with malabsorptive procedures
E	Ataxia, paresthesias, myopathy, arthropathy, anemia, retinopathy, immune dysfunction	Jejunum, ileum	Fat soluble; deficiency associated with malabsorptive procedures
K	Coagulopathy	Jejunum, ileum	Fat soluble; deficiency associated with malabsorptive procedures
Calcium	Tetany (Trousseau, Chvostek signs), paresthesias, QT prolongation, cardiac arrhythmias, petechiae, purpura, osteopenia	Duodenum, jejunum	Symptoms of acute deficiency rare; chronic deficiency common, manifests as osteopenia, related to vitamin D deficiency
Copper	Ataxia, anemia, demyelinating neuropathy, paresthesias; chronic deficiency associated with osteoporosis, cardiovascular disease, cancer	Stomach, duodenum	Involved in antioxidant metabolism
Iron	Microcytic anemia, fatigue, cold intolerance, atrophic glossitis, angular stomatitis	Duodenum	Conversion from ferric to ferrous form requires acid hydrolysis; supplements interfere with calcium absorption, should be taken at different times
Magnesium	Alopecia, muscle cramps, hypocalcemia, hypokalemia, hypoparathyroidism, chronic deficiency linked to increased risk of diabetes, cardiovascular disease	Duodenum	Deficiency common in obesity independent of surgery in up to 35% of patients
Selenium	Acute deficiency rare; chronic deficiency linked to increased risk of cancer, diabetes, long-term mortality	Duodenum	Involved in antioxidant metabolism; excess selenium is toxic
Zinc	Alopecia, dermatitis	Duodenum	Deficiency common in obesity independent of surgery in up to 50% of obese patients

Dominant anatomic sites of absorption are listed, but many micronutrients are absorbed throughout the GI tract. In cases of micronutrients absorbed via active transport mechanisms, passive absorption also occurs in lesser amounts, and supplementation with suprapharmacologic doses overcomes bypassed active uptake mechanisms via passive absorption (e.g., B12).

Hand-sewn, linear stapler, and circular stapler techniques are used to create the gastrojejunostomy in gastric bypass. No single technique demonstrates a clear advantage, although stenosis rates may be higher with the circular stapler technique. Absorbable suture should be used for all anastomoses, as

nonabsorbable suture is a nidus for ulcer formation. Routine intraoperative testing of the gastrojejunal anastomosis with EGD-air insufflation or methylene blue instillation may be associated with reduced anastomotic dehiscence rates and is advisable. The use of drains at the gastrojejunal anastomosis is practiced selectively, and no clear data demonstrate that routine drain placement aids in early detection or reduced morbidity of anastomotic dehiscence. Some data suggest that drains may allow for nonoperative management of such events. Routine closure of internal hernia defects during gastric bypass is controversial, as data do not clearly demonstrate that this practice reduces late hernia incidence. Nonetheless, closure is straightforward, entails low morbidity, and is therefore recommended. Risk–benefit analyses do not support prophylactic cholecystectomy during laparoscopic bariatric surgery in the absence of cholelithiasis, or in the presence of asymptomatic cholelithiasis. It is therefore reasonable to manage cholelithiasis in bariatric surgery patients as in all patients, that is, perform cholecystectomy only if symptoms are present.

As with any laparoscopic operation, conversion to laparotomy is a reasonable option if laparoscopy presents insurmountable technical challenges. That said, bariatric surgeons are well aware that “open” bariatric surgery is not “easier” than laparoscopic surgery, but simply presents qualitatively different technical challenges. Often, hepatomegaly is a major obstacle. Left hepatic lobe size should be assessed at the beginning of every operation, and if adequate liver retraction is not possible, consideration should be given to aborting the planned procedure, especially if significant steatosis is present that might be mitigated by further preoperative diet-induced weight loss.

Perioperative and Postoperative Management

Perioperative care of the bariatric surgery patient is similar to that of any patient undergoing complex GI surgery but must be tailored to the obese. Inpatient, outpatient, and operating room facilities should be equipped with beds, chairs, lifting and transfer apparatuses, and other equipment capable of bearing the weight of obese patients. Anesthesia, nursing, dietician, physical therapy, and other subspecialty staff with experience in the management of obese patients are necessary. Hospital stays after laparoscopic gastric bypass and sleeve gastrectomy are typically 1 to 3 days, while gastric band is generally performed on an outpatient basis.

The dietary regimen in the first few weeks after surgery is designed to prevent food impaction at an edematous surgical site and maintain adequate hydration, and includes clear liquids progressing to soft foods. Caloric intake in the early postoperative period may be less than 500 cal/day, which is acceptable as long as hydration is maintained. Within 2 to 3 weeks of surgery, solid foods may be introduced and caloric intake will slowly rise, with a long-term maintenance target of 1,200 to 1,500 calories and 50 to 70 g of protein per day. Within a few months of surgery, most patients are able to eat any foods in small quantities with few exceptions. Deviation from this pattern should raise concerns for anastomotic stenosis, ulcer, or other complications. Persistent vomiting, unless clearly associated with a specific food that when eliminated ameliorates symptoms, is abnormal and should prompt a diagnostic workup, usually with UGI and/or EGD.

The incidence of cholelithiasis after bariatric surgery ranges from 15% to over 70%, but only approximately 7% of patients will require cholecystectomy. Prophylactic treatment with ursodeoxycholic acid reduces the risk of postoperative cholelithiasis, from 28% to 9% in one recent meta-analysis. Such therapy entails little morbidity and a 6-month postoperative treatment regimen is common practice. Data are equivocal, however, regarding whether this practice reduces cholecystectomy rates or is cost-effective.

The variability in surveillance practices makes accurate estimation of the incidence of postoperative nutritional deficiencies challenging, and a wide range of supplementation practices exist. Interpretation of the data is made more difficult because obese patients are at high risk for pre-existing micronutrient deficiencies independent of surgery. Vitamin D and zinc deficiencies, for example, afflict over 50% and 30% of obese patients, respectively. Abnormal serum levels of micronutrients after surgery are common, ranging from 10% to >80% depending on the micronutrient, operation, and patient population studied; clinically symptomatic deficiencies are less common. Consensus guidelines from the American Association of Clinical Endocrinologists, the Obesity Society, and the ASMBS recommend that gastric bypass patients undergo annual surveillance of 25-hydroxyvitamin D, calcium, iron, and B12 levels, along with a complete blood count, electrolyte and lipid panels, and liver function tests and periodic bone scans, and receive lifelong daily multivitamin (including folate), calcium citrate, vitamin D, and vitamin B12 supplementation, with iron supplementation in menstruating women.²⁸ Sleeve gastrectomy patients likely have a lower risk of nutritional deficiencies, but similar regimens are

recommended. Gastric band patients receive a daily multivitamin, calcium, and vitamin D supplementation.

Clinical follow-up after bariatric surgery should be lifelong. Primary care providers play a critical role in preoperative and postoperative care. Endocrinology expertise may be required, especially in the early postoperative period when diabetes may resolve rapidly. A medical bariatrician subspecialty is evolving to care for this expanding patient population.

Physiologic Mechanisms Underlying Bariatric Surgery Efficacy

Restriction of caloric intake and nutrient malabsorption are the classic presumed mechanisms of bariatric operations. These mechanisms are important, but their relationship to outcome is complex and nonlinear. For example, data are conflicting regarding the correlation between gastric bypass pouch size and weight loss. In general, pouch volumes <50 cc are associated with good results with little evidence that smaller pouches achieve greater weight loss, while efficacy may decrease substantially as pouch sizes increase beyond 50 cc. Similarly, common channel length teeters on a less well-defined threshold, above which weight loss is poor and below which malnutrition results. Other features of restriction are counterintuitive: more rapid gastric pouch emptying on oral contrast studies is associated with greater weight loss after gastric bypass while sleeve gastrectomy is associated with increased gastric emptying rates compared to native anatomy. These observations suggest a complex relationship between weight regulation, metabolism, and gut anatomy and motility.

7 Complex mechanisms in addition to restriction and malabsorption contribute to weight loss and improved metabolism after surgery, with qualitatively different responses than those associated with diet-induced weight loss. Satiety is increased, hunger decreased, and metabolic rate increased after bariatric surgery, the opposite of responses observed with diet-induced weight loss. Bariatric surgery somehow “sidesteps” the normal compensatory responses that act to defend body weight with nonsurgical weight loss. The mechanisms underlying these counterintuitive responses are not well established. Among putative mechanisms are changes in gut hormone secretion secondary to altered intestinal anatomy. Decades ago, it was observed that an oral glucose load elicits a greater insulin response than an intravenous glucose load, leading to postulation of the existence of *incretins*, gut hormones secreted in response to a meal that regulate systemic glucose metabolism. Subsequent research led to the discovery of GIP and GLP-1, incretins secreted by duodenal K cells and ileal L cells, respectively, in response to nutrient delivery to the small intestine. Incretins have diverse effects on glucose homeostasis, potentiating central insulin secretion and peripheral insulin sensitivity. Alterations in incretin hormone secretion secondary to gut anatomic derangements were invoked to explain the observation that diabetes often improved within days of gastric bypass, well before substantial weight loss.

The *foregut and hindgut hypotheses* have been proposed to explain this phenomenon: bypass of the alimentary stream from the stomach, duodenum, and proximal jejunum (the foregut hypothesis), and increased caloric delivery to the distal jejunum and ileum (the hindgut hypothesis) alter secretion of gut hormones with improvement in glucose homeostasis. While data are less compelling for GIP and other putative foregut hormones, evidence supports the hindgut hypothesis, including data demonstrating increased serum GLP-1 levels after gastric bypass. While debate persists regarding the magnitude of these effects on diabetes remission after gastric bypass, an understanding of incretin physiology has led to the development of GLP-1 agonists as pharmacologic therapy for diabetes independent of bariatric surgery.

Gut anatomic derangements mediate additional metabolic changes. Gastric bypass and sleeve gastrectomy reduce secretion of the orexigenic hormone ghrelin from the gastric fundus, which may reduce hunger after surgery. Gastric bypass and sleeve gastrectomy are associated with increased secretion of peptide YY and oxyntomodulin, gut hormones secreted by L cells in parallel with GLP-1 in response to a meal that induce satiety and inhibit gut motility and are central mediators of the “ileal brake” mechanism. Roux-en-Y anatomy alters bile acid metabolism, increasing serum levels of conjugated bile acids with beneficial effects on glucose and lipid metabolism. Bariatric surgery disrupts vagal and enteroenteric innervations of the gut and alters CNS satiety responses. Finally, gastric bypass is associated with alterations in gut microbiota that contribute to weight loss and resolution of metabolic disease. The precise mechanisms by which these diverse effects contribute to weight loss and metabolic disease remission remain unclear.

Mechanisms other than restriction and malabsorption underlie the systemic effects of bariatric surgery. An emerging field of *metabolic surgery* is exploring operations designed to mimic the metabolic effects of gastric bypass (e.g., ileal transposition, foregut exclusion) in animals and lean diabetic humans

with promising results. Also in development are endoscopic and laparoscopic gastric plications, intragastric balloon placement, vagal nerve blockade, gastric simulators, and impermeable intraluminal duodenal and jejunal stents designed to prevent caloric absorption. Bariatric surgery in the 21st century will evolve to include a broad array of procedures applied to a diverse patient population as these efforts mature.

Chapter 47

Gastric Neoplasms

Hari Nathan and Rebecca M. Minter

Key Points

- 1 The presence of a gastric adenomatous polyp is a marker of increased risk for the development of cancer in the remaining gastric mucosa, and therefore these patients should be enrolled in an appropriate endoscopic surveillance program.
 - 2 *Helicobacter pylori* infection is the predominant risk factor for gastric carcinogenesis. However, additional cofactors also play an important role and likely drive the progression from a premalignant condition to adenocarcinoma in most individuals.
 - 3 The symptoms produced by gastric cancer are not specific and can mimic those associated with a number of nonneoplastic gastroduodenal diseases, especially benign gastric ulcer.
 - 4 The extent of gastric resection is determined by the need to obtain a resection margin free of microscopic disease, and examination of a minimum of 15 nodes is suggested for adequate staging.
 - 5 Multimodality treatment should be the standard of care for treating locally advanced resectable gastric cancer.
 - 6 Low-grade gastric MALT lymphomas are usually effectively treated with eradication of *H. pylori* infection alone.
 - 7 Almost all (95%) gastrointestinal stromal tumors (GISTs) express the KIT antigen, and this is an important molecular target for medical therapy.
-

Gastric cancer is a relatively common, frequently lethal affliction and remains a serious and unsolved problem in general surgery. The disease often is not recognized until it is at an advanced stage. Gastric cancer usually cannot be controlled by surgery alone, and surgical cure rates have remained disappointingly low. Increasingly, a multidisciplinary approach is being applied to these difficult neoplasms, with some modest improvements in outcome finally being observed. Technical innovations and basic scientific investigations continue to be applied to this disease, and cautious optimism for the future is appropriate.

ADENOCARCINOMA

Epidemiology

Starting in 1930, the incidence of gastric cancer declined dramatically in the United States. By 1990, the incidence of gastric cancer (10 cases per 100,000 population) was approximately one-fourth the incidence recorded in 1930.¹ By 2010, gastric cancer accounted for 2% of cancer deaths in the United States, compared with 20% to 30% in the 1930s.¹ Nevertheless, more than 22,000 new cases continue to be diagnosed annually in the United States, with over 10,000 deaths per year attributable to the disease. Worldwide, its impact is much larger, and gastric cancer remains the third leading cause of cancer death among men and the fifth leading cause among women, accounting for 10% of cancer deaths overall.² It has long been thought that environmental exposures play a role in gastric carcinogenesis, a notion that is supported by the finding that groups who migrate from regions with high prevalence of gastric cancer to those with low prevalence experience a decreasing incidence of gastric cancer with time.^{3,4} It has been theorized that dietary changes and reductions in smoking have contributed to decrease in gastric cancer incidence in some parts of the world.² Food preservation methods using large amounts of salt and nitrites have been partially supplanted by improved refrigeration, and fresh fruits and vegetables have become more widely available. The strongest known risk factor for gastric cancer, however, is infection with *Helicobacter pylori*, which is associated with a six-fold increased risk of (noncardia) gastric cancer.^{5,6} Approximately 75% of gastric cancer cases are attributable to *H. pylori* infection, making this

organism the dominant infectious cause of cancer in the world.⁷

Due at least in part to these environmental factors, there is marked worldwide geographic variability in the incidence of gastric cancer (Fig. 47-1).⁸ The highest incidence occurs in Eastern Asia, but Central and Eastern Europe and South America also have high incidence of gastric cancer. The lowest incidence of gastric cancer is seen in Africa and North America.² In the United States, higher gastric cancer incidence and mortality are seen in black, Asian American/Pacific Islander, American Indian/Alaska Native, and Hispanic patients as compared with non-Hispanic white patients.¹ The anatomic distribution of gastric cancers also varies, with proximal cancers occurring more commonly in relatively younger, white, and male patients.⁹

Premalignant Lesions

The risk for development of gastric cancer is greater in stomachs that harbor polyps. This risk is related most closely to polyp histologic type, size, and number. Variations in these three factors account for the wide range in reported risk associated with gastric polyps. In terms of malignant potential, gastric polyps can be divided into two broad categories—hyperplastic polyps and adenomatous polyps.

Although not premalignant, hyperplastic polyps are discussed here because they are common, occurring in up to 1% of the general population and accounting for 75% of all gastric polyps. The hyperplastic polyp contains an overgrowth of histologically normal-appearing gastric epithelium. Atypia is rare, and hyperplastic gastric polyps have no neoplastic potential. Hyperplastic polyps are generally asymptomatic. Dyspepsia and vague epigastric discomfort are the most common complaints, although coexistent gastroduodenal disease is also frequently identified. Complications are unusual, and gastrointestinal hemorrhage occurs in less than 20% of patients. When hyperplastic polyps are discovered, endoscopic removal for histologic examination is indicated and is sufficient treatment. Subsequent surveillance is not necessary, given the lack of neoplastic potential in these polyps.

Figure 47-1. Worldwide geographic variability in gastric cancer incidence. (From Ferlay J, Soerjomataram I, Ervik M, et al. *GLOBOCAN 2012 v1.0, Cancer Incidence and Mortality Worldwide: IARC CancerBase No. 11* [Internet]. Lyon, France: International Agency for Research on Cancer; 2013. Available from: <http://globocan.iarc.fr>, accessed on August 1, 2015.)

1 Adenomatous polyps also tend to be asymptomatic, but in contrast to hyperplastic polyps, adenomatous polyps carry a distinct risk for the development of malignancy.¹⁰ Mucosal atypia is frequent, and mitotic figures are more common than in hyperplastic polyps. Dysplasia and carcinoma in situ have developed in adenomatous polyps observed over time. The risk for the development of carcinoma has been estimated at 10% to 20% and is greatest for polyps more than 2 cm in diameter. The presence of multiple adenomatous polyps increases the risk of cancer. The presence of an adenomatous polyp is also a marker indicating a diffusely increased risk for the development of cancer in the remainder of the gastric mucosa.

Endoscopic removal is indicated for pedunculated lesions and is sufficient if the polyp is completely removed and shows no evidence of invasive cancer on histologic examination. Operative excision is recommended for sessile lesions larger than 2 cm, for polyps with biopsy-proved invasive carcinoma, and for polyps complicated by pain or bleeding. After removal, repeat endoscopic surveillance is indicated to rule out recurrence at the site of previous excision, evaluate for new or missed polyps or an early carcinoma, and confirm eradication of *H. pylori*, if applicable.

Gastritis

The incidence of both gastric cancer and atrophic gastritis increases with age. Chronic gastritis is frequently associated with intestinal metaplasia and mucosal dysplasia, and these histologic features are often observed in mucosa adjacent to gastric cancer. Gastritis is frequently progressive and severe in the gastric mucosa of patients with cancer.

Gastric malignancy seems to be increased in patients with chronic gastritis associated with pernicious anemia, although the risk appears to have been overstated in the past. This disease, characterized by fundic mucosal atrophy, loss of parietal and chief cells, hypochlorhydria, and hypergastrinemia, is present in 3% of people older than 60 years. For people in whom pernicious anemia has been active for more than 5 years, the risk of gastric cancer is twice that of age-matched control subjects. Patients with pernicious anemia also have an increased risk of gastric carcinoid development. This increased risk warrants aggressive investigation of new symptoms in patients with long-standing pernicious anemia, but it is not high enough to justify repeated endoscopic surveillance.

Intestinal metaplasia, the presence of intestinal glands within the gastric mucosa, is also commonly associated with both gastritis and gastric cancer. The evolution from metaplasia to dysplasia to carcinoma to invasive cancer has been demonstrated in other organs and in adenocarcinoma arising in the gastroesophageal junction. However, no direct evidence has been provided for this progression in gastric cancer.

Helicobacter Pylori

2 As outlined above, infection with *H. pylori* has been unequivocally associated with chronic inflammatory conditions in the stomach, and this association has stimulated interest in the role of chronic infection by this organism in gastric carcinogenesis. Childhood acquisition of *H. pylori* infection is frequent in areas of high gastric cancer incidence, and high rates of infection have been identified in patients with premalignant lesions and invasive cancer. Infection with *H. pylori* is associated with an increased risk of adenocarcinoma of both major histologic types (intestinal and diffuse) and of both the body and the antrum of the stomach.¹¹ In contrast, *H. pylori* infection is not a risk factor for cancers of the gastroesophageal junction, which are frequently associated with mucosal abnormalities of Barrett esophagus and which seem to follow the metaplasia to dysplasia to carcinoma pattern of development.

The mechanism of carcinogenesis related to *H. pylori* infection is incompletely understood but is thought to be related to the chronic inflammation caused by the organism.¹² However, only ~1% of patients chronically infected with *H. pylori* will develop the gastric cancer phenotype, which consists of corpus-predominant gastritis, multifocal atrophic gastritis, high gastrin levels, hypo/achlorhydria, and low pepsinogen I/II ratio. The majority of subjects infected with *H. pylori* will develop the simple gastritis phenotype which is not associated with any significant clinical outcome, or the duodenal ulcer phenotype (10% to 15% of infected subjects) which consists of antral-predominant gastritis and high gastrin and acid secretion and actually provides protection from developing gastric cancer.¹³ Of note, there is variable distribution of these three phenotypes geographically, with particular prevalence of the gastric cancer phenotype in certain parts of Asia where gastric cancer is common.¹⁴ Bacterial virulence factors, environmental exposures, and host genetic factors also clearly play an important role in the pathogenesis of gastric carcinogenesis following infection-related gastritis.^{12,13,15} Eradication of *H. pylori* may not prevent the development of gastric cancer once premalignant lesions have already developed.¹⁶

Previous Gastric Surgery

A number of uncontrolled reports have suggested that gastric cancer is more likely to develop in people who have undergone previous partial gastrectomy, with patients who have undergone a gastrojejunal (Billroth II) anastomosis at apparently higher risk for carcinogenesis than those reconstructed with a gastroduodenal anastomosis (Billroth I).^{17,18} The so-called *gastric remnant cancer* is a true clinical entity, although the risk for development of this gastric neoplasm appears to have been overestimated. Several large, prospective studies with long-term follow-up indicate that the relative risk is not increased for up to 15 years after gastric resection, likely due to surgical removal of mucosa at risk for development of gastric cancer, followed by modest increases in cancer risk (three times the control value) observed only after 25 years.^{19–22}

The cellular mechanisms that contribute to the development of neoplasia in the remnant stomach are unknown. Decreased luminal pH, bacterial overgrowth with increased production of *N*-nitroso carcinogens, and reflux of bile acids into the stomach have been postulated to promote cancer development, but remains unproved. Vagotomy, often performed in conjunction with gastric surgery for benign disease, does not appear to promote cancer development. A population-based study from Sweden

of 7,198 vagotomized patients followed for up to 18 years did not report increased risk.²⁰

A recent study explored genetic alterations in gastric remnant cancer and found that the microsatellite instability high (MSI-H) phenotype was much more common (43%) in gastric remnant cancers than in sporadic gastric cancers (6%), and that this incidence was much higher in patients who had undergone a Billroth II anastomosis (67%) as compared to those who had undergone a Billroth I anastomosis (11%). The MSI-H phenotype in these tumors was associated with inactivation of the DNA mismatch repair genes hMLH1 and hMSH2. The significance of this relationship is not yet clear.²³ Reported 5-year survival ranges from only 7% to 33% for gastric remnant cancers, but this poor prognosis is most likely due to the fact that these cancers are usually diagnosed at an advanced stage when treatment options are limited.

Hereditary Syndromes

Approximately 5% to 10% of gastric cancer may have a familial component, and 3% to 5% are associated with known inherited cancer syndromes. Hereditary diffuse gastric cancer (HDGC) is an autosomal dominant syndrome that confers a lifetime risk for the development of gastric cancer by age 80 years of 67% for men and 83% for women.²⁴ The average age at diagnosis is 37 years, and cancers tend to be of the diffuse type. Germline mutations in CDH1, a tumor suppressor gene that encodes the cell-to-cell adhesion protein E-cadherin, are found in 25% of patients with HDGC.²⁵ Patients with documented CDH1 mutations and a family history of gastric cancer may be offered prophylactic gastrectomy at a young age. Other familial cancer syndromes associated with an increased risk of gastric cancer include Lynch syndrome, juvenile polyposis syndrome, and Peutz–Jeghers syndrome. Surveillance upper endoscopy may be considered in patients with these syndromes.

Clinical Features

3 The symptoms produced by gastric cancer are nonspecific and can closely mimic those associated with a number of nonneoplastic gastroduodenal diseases, especially benign gastric ulcer (Fig. 47-2). In early gastric cancers, epigastric pain is present in over 70% of patients.²⁶ The pain is often constant, nonradiating, and unrelieved by food ingestion. In a surprising number of patients, pain can be relieved, at least temporarily, by antacids or gastric antisecretory drugs. Anorexia, nausea, and weight loss are present in less than 50% of patients with early gastric cancers but become increasingly common with disease progression. Dysphagia is present in 20% of patients with proximal gastric lesions. Overt gastrointestinal hemorrhage is present in only 5%. Perforation is uncommon (1%).

Figure 47-2. Clinical symptom frequency in benign gastric ulcer, early gastric cancer, and advanced gastric cancer. (After Meyer WC, Damiano RJ, Postlethwait RW, et al. Adenocarcinoma of the stomach: changing patterns over the past four decades. *Ann Surg* 1987;205:18.)

In most patients with early gastric cancers, physical examination is unremarkable. Stool tests positive for occult blood in one-third. Abnormal physical findings usually reflect advanced disease (Table 47-1). Cachexia, abdominal mass, hepatomegaly, and supraclavicular adenopathy usually indicate metastatic disease.²⁷ There are no simple laboratory tests specific for gastric neoplasms.

Diagnosis and Staging

Fiberoptic endoscopy is the most definitive diagnostic method when gastric neoplasm is suspected. In the initial stages, gastric cancers can appear polypoid, as flat, plaquelike lesions, or as shallow ulcers. Advanced lesions are typically ulcerated. The ulcer border can have an irregular, beaded appearance because of infiltrating cancer cells, and the base is frequently necrotic and shaggy. The ulcer can appear

to arise from an underlying mass. Although each of these features suggests a malignant ulcer, differentiation of benign from malignant gastric ulcers can be made definitively only with gastric biopsy. Multiple biopsies of any gastric ulcer should be performed. The sensitivity of a single biopsy for diagnosing a gastric cancer is 70%, but performing multiple biopsies can increase the sensitivity to greater than 98%.²⁸ False-negative results occur in approximately 10% of patients, usually as the result of sampling error or due to the absence of a mucosal abnormality as can occur with linitis plastica; false-positive results are rare. Diagnostic accuracy can be further enhanced by the addition of endoscopic ultrasound (EUS) with fine-needle aspiration biopsy for infiltrative tumors involving the wall of the stomach without obvious mucosal abnormalities.

DIAGNOSIS

Table 47-1 Common Symptoms and Physical Findings in Gastric Cancer

Symptoms	Physical Findings
Weight loss	Guaiac-positive stool
Pain	Cachexia
Nausea and vomiting	Abdominal mass
Anorexia	Abdominal tenderness
Dysphagia	Hepatomegaly
Melena	—

Figure 47-3. Early cancer survival rate in Japan.

Annual mass screening programs have been instituted in some countries (e.g., Japan, Venezuela, Chile) with high incidence of gastric cancer. Whether such programs significantly reduce gastric cancer mortality is unclear. In Japan, compliance with screening has been associated with a 50% decrease in gastric cancer mortality, but most of this benefit is attributable to confounding factors such as baseline general health.²⁹ A large cohort study failed to show any effect of screening on mortality.³⁰ Cancers detected in screened patients tend to be earlier cancers with fewer nodal metastases,³¹ and patients with resected gastric cancer diagnosed by screening have better survival than those diagnosed after development of symptoms (Fig. 47-3). However, a survival difference between screened and unscreened gastric cancer patients persists even after accounting for stage,³¹ suggesting that patient selection confounds the effect of screening on mortality. The Japanese findings that early detection and identification of early gastric cancer can improve survival has been confirmed by European

investigations, in which patients with early gastric cancers have been shown to have survival rates equivalent to those of patients with benign gastric ulcer (Fig. 47-4).²⁶ Mass screening programs have been found to be cost-effective in high-incidence countries such as Japan and China,³² but they are unlikely to be cost-effective in lower-incidence countries such as the United States. The cost-effectiveness of the Japanese screening program is likely to change given the significant decrease in the rate of chronic *H. pylori* infection in Japanese under the age of 30 (25% vs. 60% as compared to their parents).³³

Figure 47-4. Early cancer survival rate in Europe.

Barium-contrast radiographs have, in the past, been the standard method for diagnosing gastric neoplasm. Single-contrast examinations have a diagnostic accuracy of 80%. This diagnostic yield increases to approximately 90% when double-contrast (air and barium) techniques are used. Typical findings include ulceration, the presence of a gastric mass, loss of mucosal detail, and distortion of the gastric silhouette (Fig. 47-5). Contrast radiography has been largely supplanted by endoscopy because of the ability to obtain biopsy material by the latter technique.

Figure 47-5. Barium-contrast radiograph demonstrating extensive involvement of the gastric body by infiltrating adenocarcinoma (linitis plastica). The gastric silhouette is narrowed (*arrows*), and the stomach is nondistensible.

Figure 47-6. Computed tomography scan demonstrating mass along lesser curvature of the stomach (*black arrow*) and associated lymph node enlargement (*white arrow*).

Computed tomography (CT) can provide information both about the primary tumor and visceral metastatic disease. Because it is noninvasive and widely available, it is often the first staging modality that is employed in a patient diagnosed with gastric cancer. Patients who are found to have metastatic disease can be spared further, potentially invasive staging studies. When performed with intraluminal and intravenous contrast, CT can demonstrate infiltration of the gastric wall by tumor, gastric ulceration, and the presence of hepatic metastases (Figs. 47-6 and 47-7). CT may overestimate depth of invasion, but serosal involvement can be reliably assessed (sensitivity 83% to 100%, specificity 80% to 97%).³⁴ The technique is less reliable for detection of small peritoneal metastases, which may be missed in 30% of cases.³⁵ Similarly, evaluation of nodal disease by CT is limited, with accuracy of 70% to 80% even with modern CT techniques.³⁶

EUS is another useful method of preoperative evaluation for local staging and diagnosis. EUS can assess subepithelial lesions that may be confused with gastric cancer and guide biopsy of submucosal tumors within the wall of the stomach. Investigation of submucosal masses, infiltrative gastric disorders, and enlarged gastric epithelial folds, as well as differentiation of gastric lymphoma from gastric adenocarcinoma are all aided by EUS. This technique has the ability to assess the depth and pattern of gastric wall penetration by the tumor as well as relationship to adjacent structures, and has good correlation with intraoperative assessment and histologic findings. Perigastric lymph nodes involved with tumor are also reliably identified by EUS, and therefore EUS provides the most accurate assessment of local stage of disease (TN status), with an accuracy of 65% to 90% for staging depth of tumor invasion³⁴ and 50% to 78% for nodal involvement.³⁷ EUS is generally not useful for detecting metastatic disease, but it can help identify patients at risk for radiographically occult metastatic disease (e.g., peritoneal metastases) for staging laparoscopy.³⁵ Therefore, EUS serves as a useful adjunct to cross-sectional imaging and can help guide selection of patients for further staging studies or multimodality therapy.

Metabolic imaging with positive emission tomography (PET) using ¹⁸F-fluorodeoxyglucose has been found to be less accurate than cross-sectional imaging and EUS for staging locoregional involvement, but more sensitive for detecting distant metastases in patients with gastric cancer.³⁷ A meta-analysis comparing PET, ultrasound, CT, and magnetic resonance imaging (MRI) found that PET scan was the most sensitive imaging modality for detecting hepatic metastases.³⁸ A separate study found that tumors which responded metabolically on PET to neoadjuvant chemotherapy correlated highly with histopathologic response and improved patient survival.³⁹ Therefore, current recommendations regarding the use of PET for staging gastric cancer are for selective use for patients with locally advanced tumors where the metastatic potential is high, and in cases where neoadjuvant therapy is being considered.³⁷ In these patients, the addition of PET can result in net cost savings by reducing the number of futile surgical procedures.⁴⁰

Figure 47-7. Computed tomography scans of the upper abdomen showing extensive thickening of the gastric wall (*black arrows*) caused by infiltrating adenocarcinoma and associated hepatic metastasis (*white arrow*).

Staging Laparoscopy

The peritoneal lining, omentum, and liver capsule are common sites for gastric cancer metastasis that are difficult to evaluate preoperatively by CT scanning. In prospective studies, diagnostic laparoscopy has been superior to preoperative CT or percutaneous ultrasound in detection of peritoneal, hepatic, or lymphatic metastasis.⁴¹ Accurate identification of patients with metastatic disease is important in order to spare them futile, ultimately noncurative surgical procedures. In up to 25% of patients, laparoscopy will detect metastatic disease that precludes curative resection.^{42–44} Relative to laparotomy, the shorter hospitalization and reduced operative trauma following laparoscopy may both hasten recovery and facilitate earlier initiation of systemic chemotherapy. Most patients with systemic metastasis can be treated without the need for palliative surgical resection.⁴⁵

In addition to grossly evident intra-abdominal metastatic disease, patients with microscopic metastatic disease are at high risk for early recurrence and death after attempted curative resection.^{46,47} Based on this finding, patients with positive cytology in peritoneal washings are considered to have M1 disease. Approximately one-fourth of patients subjected to staging laparoscopy prior to planned curative resection of gastric cancer will have positive peritoneal cytology; one-third of these patients will not have grossly apparent metastatic disease. Patients who clear their initially positive peritoneal cytology after systemic chemotherapy have an improved prognosis, but cure remains highly unlikely.⁴⁶

Diagnostic laparoscopy may be considered in patients being considered for surgical resection without neoadjuvant therapy. In these situations, the procedure can be conducted at the beginning of the planned resection so as to avoid an additional general anesthesia. Patients with locally advanced (T3–T4 or node-positive) tumors who would typically be selected for neoadjuvant therapy should be considered for diagnostic laparoscopy with peritoneal washings prior to initiation of chemotherapy. The finding of positive peritoneal cytology should prompt adoption of a noncurative paradigm of treatment in most cases.

Pathology

Gastric adenocarcinoma occurs in two distinct histologic subtypes—intestinal and diffuse. These subtypes are characterized by differing pathologic and clinical features and by differing patterns of metastatic spread.

In the intestinal form of gastric cancer, the malignant cells tend to form glands. The intestinal form of malignancy is more frequently associated with gastric mucosal atrophy, chronic atrophic gastritis, intestinal metaplasia, and dysplasia. Gastric cancer with the intestinal histologic subtype is more common in populations at high risk (e.g., Japan), and it occurs with increased frequency in men and older patients. Clinical studies suggest that this subtype more frequently demonstrates bloodborne metastases.

The diffuse form of gastric adenocarcinoma does not demonstrate gland formation and tends to infiltrate tissues as a sheet of loosely adherent cells. Lymphatic invasion is common. Intraperitoneal metastases are frequent. The diffuse form of gastric adenocarcinoma tends to occur in younger patients, in women, and in populations with a relatively low incidence of gastric cancer (e.g., the United States). The prognosis is poorer for patients with the diffuse histologic subtype.

Sporadic gastric adenocarcinomas demonstrate a number of chromosomal and genetic abnormalities. Cytometric analysis reveals that gastric tumors with a large fraction of aneuploid cells (with a greater-than-normal amount of nuclear DNA) tend to be more highly infiltrative and have a poorer prognosis. Amplifications of both the *HER-2/neu* and *K-ras* proto-oncogenes have been consistently detected in gastric adenocarcinomas, and in a small percentage of tumors a lack of expression of the tumor suppressor gene *MLH1* is robustly associated with poor survival.⁴⁸ The exact mechanisms by which these genetic abnormalities contribute to gastric oncogenesis are currently unclear. Additionally, a number of growth factors, including epidermal growth factor, platelet-derived growth factor, and transforming growth factor- β , are overexpressed in gastric carcinoma cells.⁴⁹

In the United States, the incidence of proximal gastric cancers has been increasing; such that in 2001 the rate of proximal cancers, defined as cancers arising in the cardia and fundus, exceeded that of distal cancers, defined as cancers arising in the antrum and pylorus. Proximal cancers are more likely to occur in young white men and distal cancers are more likely to occur in Asian, African American, and Hispanic patients within the United States. The proportion of tumors involving the proximal stomach has dramatically increased over the past decades; in the 1960s, only 16% involved this region, and a clear explanation for this rise in proximal disease remains elusive. In 10% of cases, the stomach is diffusely involved at the time of diagnosis.²⁷ Prognosis is poorer for tumors arising from the proximal stomach or for those with diffuse involvement of the organ relative to distal tumors, and these patients are much more likely to need neoadjuvant and adjuvant therapy.^{9,50}

CLASSIFICATION AND STAGING

Table 47-2 Seventh Edition AJCC Staging System for Gastric Cancer

Primary Tumor	
T0	No evidence of primary tumor
Tis	Carcinoma in situ; intraepithelial tumor without invasion of the lamina propria
T1a	Tumor invades lamina propria or muscularis mucosae
T1b	Tumor invades submucosa
T2	Tumor invades muscularis propria
T3	Tumor penetrates subserosal connective tissue without invasion of visceral peritoneum or adjacent structures
T4a	Tumor invades serosa (visceral peritoneum)
T4b	Tumor invades adjacent structures
Regional Lymph Node Involvement	
N0	No regional nodal metastasis
N1	Metastasis to 1–2 regional lymph nodes
N2	Metastasis to 3–6 regional lymph nodes
N3	Metastasis in 7 or more regional lymph nodes
Distant Metastasis	
M0	No distant metastasis
M1	Distant metastasis
Stage Grouping	
Stage 0	Tis N0 M0
Stage IA	T1 N0 M0
Stage IB	T1 N1 M0 T2 N0 M0
Stage IIA	T1 N2 M0 T2 N1 M0 T3 N0 M0
Stage IIB	T1 N3 M0 T2 N2 M0 T3 N1 M0 T4a N0 M0
Stage IIIA	T2 N3 M0 T3 N2 M0 T4a N1 M0
Stage IIIB	T3 N3 M0 T4a N2 M0 T4b N1 M0 T4b N0 M0
Stage IIIC	T4a N3 M0 T4b N3 M0 T4b N2 M0
Stage IV	Any T Any N M1

The seventh edition American Joint Committee on Cancer (AJCC) staging system for gastric cancer is presented in [Table 47-2](#).⁵¹ The staging system accurately discriminates prognosis based on pathologic factors for tumors located 5 cm distal to the esophagogastric junction (EGJ) and below or arising within 5 cm of, but not crossing, the EGJ ([Fig. 47-8](#)). The AJCC recommends that cancers arising within 5 cm of the EGJ that cross into the EGJ or esophagus be staged and treated as esophageal cancers. A consideration of staging data illustrates the high frequency with which lymph node metastases are present at the time of diagnosis in the United States, and the severe impact lymphatic involvement has on survival. Even early gastric cancers (tumors restricted to the mucosa and submucosa) have a 15% prevalence of nodal metastasis.

Curative-Intent Treatment

Surgical resection is the only potentially curative therapy for gastric cancer, but an advanced stage of disease at the time of diagnosis precludes curative resection for most patients.

Since the mid-1990s, the surgical treatment of gastric cancer has continued to evolve, with minimally invasive approaches increasingly pursued for early cancers and increasingly radical operations advocated by some for advanced tumors. Japanese surgeons have reported the largest experience with early gastric cancer. The Japanese Gastric Cancer Association defines early gastric cancer as tumor in which invasion is restricted to the mucosa or submucosa.⁵² The presence or absence of lymph node

metastasis is not considered in this classification. While the presence of lymphatic metastasis cannot be correctly judged by endoscopic findings, it is critically important in prognosis. For tumors confined to the mucosa, lymphatic metastasis is present in 1-3% of cases; with submucosal involvement, the rate of nodal positivity increases to 14-20%.^{53,54}

Endoscopic Resection

For intestinal-type mucosal tumors less than 2 cm in size without ulceration or evidence of lymphovascular invasion, endoscopic mucosal resection (EMR) may be performed. With this approach, postoperative bleeding or perforation has been reported in 5%, and in 17% histologic examination revealed submucosal invasion that required further operative treatment.⁵⁵ Earlier reports suggested underestimation of tumor invasion in 45% and missed lymphatic metastasis in 9% urged caution before widespread acceptance of this technique.⁵⁶ However, in experienced centers good results can be obtained. A Japanese series of 131 patients reported disease-free survival of 99% at 10 years.⁵⁷ Endoscopic submucosal dissection (ESD) is an emerging technique that may allow larger tumors to be endoscopically resected than with EMR. In the absence of randomized trials comparing EMR and ESD against surgical resection, surgical resection remains the gold standard for potentially curative therapy in appropriate-risk patients.

Surgical Resection

4The fundamental principle of surgical resection of gastric cancer is complete extirpation of the primary tumor. The extent of gastric resection is determined primarily by the need to obtain a resection margin free of microscopic disease (R0 resection). Microscopic involvement of the resection margin by tumor cells (R1 resection) is associated with poor prognosis.²⁷ Patients with positive surgical margins are at high risk for development of recurrent disease, and histologically positive margins are strongly correlated with the development of anastomotic recurrence. In the setting of ≥ 5 positive nodes, however, margin positivity does not impact survival,⁵⁸ because these patients are at higher risk for systemic recurrence. In contrast to other gastrointestinal malignancies such as colon cancer, gastric cancer frequently demonstrates extensive intramural spread, especially the diffuse type. The propensity for intramural spread is related, in part, to the extensive anastomosing capillary and lymphatic network in the wall of the stomach. Retrospective studies suggest that when performing a subtotal gastrectomy, a margin of 6 cm from the tumor mass proximally and 3 to 5.9 cm distally is necessary to minimize anastomotic recurrence.⁵⁹ Frozen section evaluation of resection margins may be obtained prior to proceeding with reconstruction in order to improve the probability that R0 resection can be achieved.

Figure 47-9. Surgical options for resection of gastric neoplasms. **A:** Subtotal gastrectomy with gastrojejunal reconstruction. **B:** Total gastrectomy with esophagojejunostomy. **C:** Esophagogastrectomy with anastomosis in cervical or thoracic position.

Figure 47-10. Postoperative radiograph after total gastrectomy with esophagojejunal anastomosis, showing esophagus (E) and jejunum (J).

For lesions in the distal two-thirds of the stomach, distal subtotal gastrectomy is usually sufficient for complete removal of the primary tumor. In contrast, lesions in the upper third of the stomach may require total gastrectomy or esophagogastrectomy to encompass the tumor (Figs. 47-9 and 47-10). For tumors involving the cardia without involvement of the gastroesophageal junction, some have advocated proximal gastrectomy as an alternative to total gastrectomy with esophagojejunostomy with the goal of preserving a gastric reservoir to lessen postoperative weight loss. This procedure does not compromise oncologic outcomes,^{60,61} but there is a significantly higher incidence of severe reflux esophagitis with proximal gastrectomy.³⁷ Use of a jejunal interposition has been proposed to mitigate reflux esophagitis, but quality-of-life data are conflicting.

Radical gastric operations can be performed with acceptable morbidity and low mortality rates in the older age groups at greatest risk for gastric cancer. Mortality rates for total gastrectomy range from 3% to 7%.⁶² There is some evidence that outcomes are superior at higher-volume centers. Defining what constitutes a high-volume center is problematic, but one review suggests that hospitals with at least 21 gastric cancer resections per year may achieve optimal outcomes.⁶³ Nutritional support in the immediate postoperative period is an important adjunctive measure as patients resume oral intake,⁶⁴ and many surgeons place a jejunal feeding tube at the time of total gastrectomy to ensure that optimal enteral nutrition can be delivered in the postoperative period. Surgical reconstructions that interpose a small intestinal reservoir between the esophagus and the jejunum have been advocated after total gastrectomy, but a clear nutritional benefit has not been demonstrated.⁶⁵⁻⁶⁸

Because gastric cancer metastasizes so frequently to lymph nodes, radical extirpation of draining lymph nodes has both therapeutic and staging implications.⁶⁹ The value of routine-extended lymphadenectomy beyond the perigastric lymph nodes in the treatment of gastric adenocarcinoma, however, is controversial. The first favorable experience was reported from Japan.^{70,71} Resections in the original Japanese system are shown in Table 47-3, and the current nomenclature used to define extent of lymphadenectomy is shown in Table 47-4 and Figure 47-11. Only retrospective studies of extended perigastric lymphadenectomy have been reported from Japan. Initial reports suggested an improvement of approximately 10%, stage for stage, for patients with advanced disease treated with D2 or D3 operations.⁷⁰⁻⁷³ The benefits of extended lymphadenectomy have not been confirmed in non-Japanese centers, and several randomized trials in Western centers have failed to show a survival benefit for extended lymphadenectomy when the entire patient population was analyzed.⁷⁴⁻⁷⁸ Long-term (median 15-year) follow-up results from the Dutch trial of D1 versus D2 lymphadenectomy have shown a lower gastric cancer–related death rate in the D2 group (37% vs. 48%) and lower rates of local and regional recurrence.⁷⁹ The significance of this finding is unclear given the absence of an overall survival benefit and the long period of time it took for this difference to manifest. Improvements in adjuvant therapy also complicate the interpretation of historical results of extended lymphadenectomy.

Table 47-3 Lymphadenectomy Resections in the Original System of the Japanese Research Society for Gastric Cancer

Level	Description
R1	Resection of stomach, omentum, and perigastric lymph nodes
R2	Resection of stomach, omentum, and en bloc removal of the superior leaf of the transverse mesocolon, the pancreatic capsule and lymph nodes along the branches of the celiac artery and in the infraduodenal and supraduodenal areas
R3	Resection of the above structures plus lymph nodes along the aorta and esophagus, along with the spleen and the tail of the pancreas, and skeletonization of vessels in the porta hepatis

The safety of extended lymphadenectomy is disputed. Data from a national Japanese registry indicate a contemporary mortality of less than 1%.⁸⁰ Low mortality risks have been reported from multi-institutional trials conducted in Italy and Germany.^{78,81} Investigations from the United States, Britain, and the Netherlands have been less optimistic, indicating increased short-term morbidity and in-hospital mortality.^{74,75}

Table 47-4 Current Nomenclature Used to Describe the Extent of Lymphadenectomy Performed in Conjunction with Gastrectomy

Level	Description
D0	Any lymph node removal that is less than D1
D1	Resection of greater and lesser omenta, including the perigastric nodes along the right and left cardia, nodes along the lesser and greater curvatures, suprapyloric nodes along the right gastric artery, and infrapyloric nodes
D2	D1 dissection plus nodes along the left gastric artery, common hepatic artery, celiac trunk, splenic hilum, and splenic artery
D3	D2 dissection plus nodes in the hepatoduodenal ligament, retropancreatic nodes, and nodes at the root of the mesentery the para-aortic lymph nodes
D4	D3 dissection plus paracolic and para-aortic nodes

N1 Lymph nodes (perigastric)

- 1 Right cardiac nodes
- 2 Left cardiac nodes
- 3 Nodes along the lesser curvature
- 4d Lymph nodes along the short gastric and the left gastroepiploic vessels
- 4s Lymph nodes along the right gastroepiploic vessels
- 5 Suprapyloric nodes
- 6 Infrapyloric nodes

N2 Lymph nodes (celiac axis branches)

- 7 Nodes along root left gastric artery
- 8 Nodes along common hepatic artery
- 9 Nodes around celiac axis
- 10 Nodes at splenic hilum
- 11 Nodes along splenic artery

N3 Lymph nodes

- 12 Nodes at the hepatoduodenal ligament
- 13 Retropancreatic (periduodenal) nodes
- 14 Nodes at the root of the mesentery

N4 Lymph nodes

- 15 Nodes along the middle colic vein
- 16 Para-aortic nodes

Figure 47-11. Lymph node locations and groupings. D1 dissection: removal of N1 nodes. D2 dissection: removal of N1 and N2 nodes. D3 dissection: removal of N1, N2, and N3 nodes. D4 dissection: removal of N1–N4 nodes.⁷⁹

Histologically positive lymph nodes are frequently present in the splenic hilum and along the splenic artery, and routine splenectomy has been practiced in some centers. Splenectomy has not been demonstrated to improve outcome for similarly staged patients.^{82,83} Likewise, resection of the tail or body of the pancreas has not been demonstrated to improve survival. Thus, associated splenectomy or pancreatosplenectomy is only beneficial when there is direct extension or bulky adenopathy at the splenic hilum.⁸⁴ Resection of adjacent organs may be required for local control if direct invasion has occurred. In this circumstance, operative morbidity is increased and the long-term survival rate is approximately 25%.⁸⁵

In some centers in the United States, greater emphasis has been placed on the total number of nodes removed and histologically examined rather than the location of the nodes (e.g., D1 vs. D2 lymphadenectomy). Current recommendations of the AJCC staging for gastric cancer suggest that a minimum of 15 nodes be evaluated for accurate staging.⁵¹

Laparoscopic gastrectomy has also been reported for treatment of gastric malignancy, with advantages of reduced pain, shorter hospitalization, and improved quality of life,⁸⁶ and studies from Japan, Korea, and Italy have demonstrated that distal, subtotal, and total gastrectomy with lymphadenectomy is feasible with acceptable morbidity and mortality. However, the majority of the patients in these studies had early gastric cancer.³⁷ A meta-analysis of four small single-institution randomized trials from Asia demonstrated lower nodal harvests with a laparoscopic approach for early gastric cancer. Complication rates were lower in the laparoscopic group but did not translate into differences in time to oral intake or length of stay.⁸⁷ A single-institution Western randomized trial of laparoscopic versus open subtotal gastrectomy for distal gastric cancer (both early and locally advanced) did report equivalent lymph node retrieval (33.4 ± 7.4 in the open group vs. 30 ± 14.9 in the laparoscopic group), as well as similar rates of perioperative morbidity and mortality. Five-year overall and disease-free survival were also similar for both groups: 55.7% and 54.8% for the laparoscopic group versus 58.9% and 57.3% for the open group.⁸⁸ More recently, interim results of a Korean multicenter randomized trial focused on early gastric cancer demonstrated equivalent perioperative morbidity and mortality, but no data on oncologic outcomes have been published to date.⁸⁹ As such, there are still no published multi-institutional randomized data to confirm the oncologic equivalency of laparoscopic gastrectomy as compared with the open approach.

Neoadjuvant and Adjuvant Therapies

5 Given the largely disappointing outcomes of locally advanced gastric cancer in Western countries, significant interest has focused on the use of multimodality therapy. Several neoadjuvant and adjuvant approaches have been explored. Although there is no consensus on the optimal approach, it is clear that all patients with locally advanced disease should be considered for multimodality therapy. Two general approaches are popular in the West.

Adjuvant chemoradiotherapy may be considered both for patients known to have locally advanced disease from the outset as well as for those thought to have early gastric cancer who are subsequently upstaged after surgical resection. The largest ($n = 556$) and most recent trial evaluating this approach was the US Intergroup INT0116 trial, which compared surgical resection followed by 5-fluorouracil (5FU), leucovorin, and external beam radiation versus resection alone in patients with gastric or EGJ cancer.⁹⁰ Most patients (69%) had T3/T4 tumors, and 85% had nodal metastases. Three-year overall survival (50% vs. 41%) and 5-year overall survival (43% vs. 28%) were significantly improved with multimodality therapy. Both local and distant failures were reduced by chemoradiation. The primary criticism of this trial was that the extent of lymphadenectomy was not standardized, and less than D1 lymph node dissection was performed in 54% of the patients, which may have contributed to the poor outcomes in the surgery-only group and led to overstatement of the true benefit of chemoradiation. Additionally, one-third of patients were unable to complete their adjuvant chemoradiation due to perioperative complications or treatment-associated toxicities. Finally, due to changes in the staging system for gastric cancer, the benefit of this regimen for patients with T2N0 disease is questionable.

A more common approach in Europe is to administer preoperative chemotherapy, with or without additional postoperative chemotherapy. The most influential trial evaluating this approach was the Medical Research Council Adjuvant Gastric Infusional Chemotherapy (MAGIC) trial, which randomly assigned 503 patients with gastric, distal esophageal, or EGJ adenocarcinomas to surgery plus

perioperative chemotherapy or surgery alone.⁹¹ Planned chemotherapy consisted of three preoperative and three postoperative cycles of epirubicin, cisplatin, and 5FU (ECF regimen). Patients with T2 and higher tumors were eligible. This study demonstrated a significant survival benefit in patients receiving perioperative chemotherapy (5-year survival 36% vs. 23%), with reduced local and distant failures. Extent of lymphadenectomy was improved as compared to the Intergroup trial, but there were significantly more patients with T1/2 tumors and N0/1 disease in the perioperative chemotherapy group, suggesting a baseline imbalance in prognosis. Additionally, only 42% of patients completed all courses of chemotherapy. Finally, as with the Intergroup trial it is unclear whether T2N0 patients are as likely to benefit from this approach as those with more advanced disease. Despite the limitations of these studies, the improved survival observed in both trials makes it clear that a multimodality approach is superior to surgery alone. Numerous ongoing studies are investigating the relative benefits of various chemotherapeutic regimens as well as the incremental benefit of chemoradiotherapy versus chemotherapy alone. Targeted therapies are also being investigated. For example, the Trastuzumab for Gastric Cancer (ToGA) trial demonstrated a modest but statistically significant survival benefit with the addition of trastuzumab to cytotoxic chemotherapy in patients with HER2-positive gastric cancer.⁹² Patients with locally advanced resectable gastric cancer are optimally treated in a center where a collaborative multidisciplinary treatment approach can be devised and executed ([Algorithm 47-1](#)).

Palliative Treatment

When preoperative evaluation demonstrates disseminated disease, palliation of symptoms becomes a primary consideration. Palliation does not usually require surgery. Obstruction and bleeding can be managed nonoperatively with endoscopic techniques or radiotherapy in selected patients. Dysphagia and bleeding caused by proximal lesions can also be alleviated endoscopically (laser therapy or stenting) in the majority of patients. Nonetheless, for a minority of patients, surgical palliation may be indicated. In the setting of metastatic gastric cancer, palliative resection does not improve survival. Noncurative resection may be indicated, for example, in the setting of intractable bleeding from the primary tumor. Surgical palliation of obstructive symptoms (resection or gastrojejunostomy) should generally be reserved for cases in which less invasive methods are contraindicated, technically infeasible, or unsuccessful. In addition to radiotherapy and endoscopic ablation or stenting, placement of a feeding jejunostomy tube with or without venting gastrostomy may be used to palliate gastric outlet obstruction, especially in patients with limited life expectancy.

Algorithm 47-1. Treatment of gastric adenocarcinoma.

GASTRIC LYMPHOMA

Clinical Features

The stomach is the site of more than half of gastrointestinal lymphomas and is the most common organ involved in extranodal lymphomas. Non-Hodgkin lymphomas account for approximately 5% of malignant gastric tumors; lymphoma represents an increasing proportion of gastric neoplasms diagnosed currently. Patients are considered to have primary gastric lymphoma if initial symptoms are gastric and the stomach is exclusively or predominantly involved with the tumor. Patients who do not fulfill these criteria are considered to have secondary gastric involvement from systemic lymphoma.

Gastric lymphoma is distinctly uncommon in children and young adults. The peak incidence is in the sixth and seventh decades. Symptoms are usually indistinguishable from those of peptic ulcer disease and gastric adenocarcinoma. Epigastric pain, weight loss, anorexia, nausea, and vomiting are common.⁹³ Systemic B symptoms such as fever and night sweats occur in a minority of patients but may be suggestive of the diagnosis. Although gross bleeding is uncommon, occult hemorrhage and anemia are observed in more than half of patients. Patients rarely have spontaneous perforation.

Diagnosis

Radiologic findings are similar to those for adenocarcinoma (gastric thickening and lymphadenopathy). Endoscopic examination is the diagnostic method of choice. The endoscopic appearance of lesions may be ulcerated, polypoid, or infiltrative, and this morphology may be further characterized by EUS. Gastric lymphoma is most commonly localized to the middle or distal stomach and unusually involves the proximal stomach, in contrast to gastric adenocarcinoma. Endoscopic biopsy, combined with endoscopic brush cytology and EUS, provides positive diagnosis in 90% of cases. Submucosal growth without ulceration of the overlying mucosa can occasionally render endoscopic biopsy nondiagnostic. EUS-guided biopsy is useful in this circumstance.

Appropriate staging should search for evidence of systemic disease. CT of the chest and abdomen (to detect lymphadenopathy), bone marrow biopsy, and biopsy of enlarged peripheral lymph nodes are all appropriate.

Mucosa-Associated Lymphoid Tissue

The concept that low-grade gastric lymphomas have features resembling mucosa-associated lymphoid tissue (MALT) is a major advance in the understanding of gastric lymphomas. The gastric submucosa does not ordinarily contain lymphoid tissue, and the development of lymphoid tissue resembling small intestinal Peyer patches is believed to occur in response to infection with *H. pylori*.⁹⁴ A number of observations support a causal relationship between chronic *H. pylori* infection and gastric lymphoma development. *H. pylori* is present in the stomachs of more than half of patients with gastric lymphoma⁹⁵ and 90% of those with gastric MALT lymphoma.⁹⁶ As with gastric adenocarcinoma, geographic regions with a high prevalence of *H. pylori* also have a high incidence of gastric lymphoma. Infection with *H. pylori* has been noted to precede development of gastric lymphoma.⁹⁷

Gastric MALT lymphoma is postulated to begin with chronic inflammation due to infection with *H. pylori*. Chronic gastritis leads to the accumulation of CD4+ lymphocytes and B cells in the gastric lamina propria. *H. pylori*-derived antigens drive T-cell activation, interleukin-2 (IL-2) release, and B-cell proliferation.⁹⁸ Progressive genetic rearrangements lead to IL-2-independent B-cell proliferation. With cumulative genetic defects, low-grade MALT lymphoma progresses to high-grade disease.

Low-grade MALT lymphomas resemble Peyer patches. Lymphoma cells invade between follicles and into gastric epithelium; invasion of gastric glands forms characteristic lymphoepithelial lesions. Low-grade lesions are often multifocal. Low-grade MALT lesions are less likely than high-grade tumors to invade transmurally, involve perigastric lymph nodes, or invade adjacent organs.⁹⁷ Approximately 40% of gastric lymphomas are low-grade MALT lymphomas.⁹⁹

6 The concept that low-grade lymphoma depends on continued *H. pylori* antigenic stimulation supports eradication of *H. pylori* with antibiotics as first-line antineoplastic therapy. Complete regression of low-grade gastric MALT lymphomas with antibiotic treatment has been reported in 70% to 100% of cases.^{100,101} The median time to complete response is 5 months.¹⁰² Most patients with partial responses were subsequently determined also to have foci of high-grade lymphoma. Radiation and chemotherapy have been proposed as salvage for antibiotic treatment failures or for the minority of patients with *H. pylori*-negative gastric MALT lymphoma.

Non-MALT Lymphomas

Most non-MALT gastric lymphomas are diffuse large B-cell lymphomas (DLBCL), including those that were previously called “high-grade MALT lymphomas.” DLBCL typically exhibit more aggressive behavior and worse prognosis than MALT lymphomas. Other histologies, such as mantle cell, follicular, and peripheral T-cell lymphomas can also be seen. Survival for gastric lymphoma is closely linked to stage at diagnosis (Fig. 47-12). In the past, a multimodality treatment program was used in most centers for primary gastric lymphomas, with gastrectomy as the first step in the therapeutic strategy.¹⁰³ This approach evolved empirically, without prospective data to support it. Several advantages of this approach had been cited: (a) more accurate histologic evaluation was possible; (b) in cases with localized tumor, the procedure could be curative; and (c) gastrectomy eliminated the risk of life-threatening hemorrhage or perforation which may occur with the treatment of tumors involving the full thickness of the gastric wall.¹⁰⁴ However, the role of gastrectomy for both staging and treatment of gastric lymphoma has diminished significantly, based in part on results of a randomized trial demonstrating superior outcomes with CHOP (cyclophosphamide, doxorubicin, vincristine, and prednisone) chemotherapy than with surgery, surgery plus radiotherapy, or surgery with CHOP (Fig. 47-13).¹⁰⁵ It has also been recognized that the incidence of perforation during chemotherapy is only 5%. Most patients are currently treated with chemotherapy (commonly CHOP with rituximab) with or without radiotherapy. Surgical intervention is generally reserved for complications such as obstruction, bleeding, or perforation.

Figure 47-12. Survival with gastric lymphoma, by stage.

Figure 47-13. Relapse-free survival by treatment assignment for primary gastric diffuse large B-cell lymphoma.

GASTRIC CARCINOIDS

Gastric carcinoid tumors were previously considered to be very rare tumors, but more recent studies have reported that as many as 10% to 30% of all carcinoids occur in the stomach, and they account for at least 1% of all gastric neoplasms.¹⁰⁶ Most patients with small gastric carcinoids are asymptomatic, and these tumors are most commonly diagnosed incidentally. Occasionally, however, larger tumors can present with abdominal pain, bleeding, or symptoms related to the secretion of bioactive substances which can be produced by the tumor. When viewed endoscopically at an early stage, carcinoids are reddish-pink to yellow submucosal nodules in the proximal stomach. Endoscopic biopsy is usually diagnostic if deep enough to sample submucosal tumor cells.

Four types of gastric carcinoids have been described. Type 1 is the most common (70% to 80%) and is

associated with chronic atrophic gastritis and pernicious anemia. These tumors tend to be small (<1 cm) and multiple, and their behavior indolent. When they are less than 2 cm in size, they metastasize less than 10% of the time.¹⁰⁷ They can typically be followed and removed endoscopically, but surgery may be necessary for larger or very numerous tumors. Type 2 tumors comprise approximately 5% of gastric carcinoids and occur in patients with Zollinger–Ellison syndrome (gastrinomas), often in the setting of multiple endocrine neoplasia type 1 (MEN1). Like type 1 tumors, they are often small, multiple, and indolent, and they can be treated endoscopically for the most part. Both type 1 and type 2 gastric carcinoid tumors are associated with hypergastrinemia. Type 1 and 2 gastric carcinoids arise from enterochromaffin-like (ECL) cells, which mediate the secretion of histamine and in turn stimulate parietal cells to secrete acid. Hypergastrinemia (due to chronic atrophic gastritis in type 1 and gastrinoma in type 2) is thought to cause ECL cell hyperplasia and lead to the development of gastric carcinoids over time.¹⁰⁸

Type 3 lesions account for 20% of gastric carcinoids. Type 3 gastric carcinoids tend to be larger, solitary lesions. They are associated with normal gastrin levels and behave much more aggressively than other gastric carcinoid tumors.¹⁰⁸ Metastases are common, and these tumors can cause an atypical carcinoid syndrome. Type 3 carcinoids are best dealt with by resection and lymphadenectomy, the extent of which depends on the size of the tumor.

GASTROINTESTINAL STROMAL TUMORS OF THE STOMACH

Gastrointestinal stromal tumors (GISTs) were historically misclassified as leiomyomas, leiomyosarcomas, and leiomyoblastomas due to a mistaken belief that they arose from the smooth muscle in the bowel wall. However, it is now recognized that GISTs represent a distinct mesenchymal tumor type, and actually arise from the interstitial cells of Cajal, intestinal pacemaker cells located in and around the myenteric plexus in the bowel wall. While GISTs can arise anywhere within the gastrointestinal tract, approximately 50% of these tumors are found in the stomach. With a slight male predominance, GISTs are typically present in middle-aged and elderly individuals, with a median age at presentation of approximately 60. They are typically asymptomatic and are most commonly identified incidentally during endoscopy performed for other reasons. Their endoscopic appearance is that of a submucosal mass with normal overlying mucosa. If these tumors become large, however, they may present with symptoms of abdominal pain and bleeding. GISTs frequently have prominent extraluminal growth patterns, and central necrosis is common as these tumors become very large and outgrow their blood supply (Fig. 47-14). If the majority of the growth is extraluminal, endoscopic examination may be unrevealing or only demonstrate umbilication of the mucosa suggestive of an underlying mass. EUS or CT imaging may be helpful for diagnosis in these cases. With large tumors, symptoms related to mass effect may occur. Additionally, ulceration of the overlying gastric mucosa may occur with tumor necrosis, and these patients may present with significant and intermittent gastrointestinal hemorrhage.

Figure 47-14. CT scan of GIST of stomach arising from lesser curvature. The *arrow* indicates central tumor necrosis. The lesion caused mucosal erosion with gastrointestinal hemorrhage.

7 The molecular hallmark of GISTs is overexpression of the CD117 antigen, which is part of the KIT transmembrane receptor tyrosine kinase. Mutations in *c-kit*, the proto-oncogene that encodes KIT, can lead to constitutive activation of the receptor and abnormal cell proliferation. Approximately 95% of GISTs overexpress KIT. Of those that do not, many have activating mutations in platelet-derived growth factor receptor alpha (PDGFRA), another receptor tyrosine kinase. However, some GISTs lack mutations

in either of these genes, and many of these are characterized by inactivating mutations in the succinate dehydrogenase (SDH) complex. The molecular pathogenesis of GIST is important because of the availability of tyrosine kinase inhibitors (TKIs), such as imatinib and sunitinib, which can inhibit GIST cell growth. However, GISTs that lack KIT or PDGFRA mutations, as well as those with certain types of KIT or PDGFRA mutations, may be variably resistant to TKI therapy.

All GISTs should be considered potentially malignant, especially those >1 cm in size.¹⁰⁹ Tumor size and mitotic index are the most important prognostic variables (Table 47-5).¹¹⁰ Site of origin is also prognostic, with gastric GISTs behaving less aggressively than intestinal GISTs.¹¹¹ For localized GISTs, surgical resection is the treatment of choice. When GISTs do metastasize, they do so by a hematogenous route (most commonly to peritoneal surfaces and the liver). Therefore, associated lymphadenectomy is typically not performed at the time of gastric resection for GIST. Additionally, unlike adenocarcinoma, GISTs do not present with an intramural growth pattern and thus gross margins of 1 to 2 cm are deemed adequate for resection of a GIST. Ultimately the goal of resection is a negative microscopic margin. If the tumor involves adjacent structures, then en bloc resection of nonvital structures should be performed whenever possible. Due to the less radical nature of surgery required for appropriate oncologic resection of these tumors as compared to adenocarcinoma of the stomach, minimally invasive surgical techniques have become widely accepted as an appropriate and acceptable operative approach for these tumors. A nomogram has been developed to allow prediction of outcomes following surgical resection of GISTs.¹¹²

For patients with metastatic or locally advanced, unresectable GISTs, imatinib is first-line therapy. Although most patients will respond to imatinib therapy, development of resistance is common, likely due to selection of clones with secondary KIT mutations.^{113,114} These patients may be managed either with imatinib dose escalation or by using another TKI (e.g., sunitinib). Imatinib is also indicated in the adjuvant setting for tumors at high risk for recurrence. The ACOSOG Z9001 trial evaluated the efficacy of 1 year of adjuvant imatinib versus placebo in patients with resected GIST ≥3 cm in size and KIT-positive.¹¹⁵ Recurrence-free survival at 1 year was significantly lower in the imatinib arm (98% vs. 83%). No overall survival difference was shown, likely because patients were allowed to cross over to the imatinib arm after the study was unblinded. The Scandinavian Sarcoma Group evaluated the effect of 1 versus 3 years of adjuvant imatinib after resection of high-risk GIST and found differences in 5-year recurrence-free survival (66% vs. 49%) and overall survival (92% vs. 82%).¹¹⁶ Based on these data, 3 years of imatinib therapy are recommended after resection of high-risk GIST. Rates of recurrence after discontinuation of imatinib therapy are similar to those in untreated patients, suggesting that TKI therapy may simply be delaying recurrences rather than actually preventing them. The use of imatinib in the neoadjuvant setting has been reported in retrospective series and was found to be safe in a phase II trial, but there are currently insufficient prospective data to guide this treatment approach.

CLASSIFICATION AND STAGING

Table 47-5 Risk of Aggressive Behavior in Gastrointestinal Stromal Tumors

Risk	Size (cm)	Mitotic Count (per 50 HPF)	Primary Tumor Site
Very low	<2.0	≤5	Any
Low	2.1–5.0	≤5	Any
Intermediate	2.1–5.0	>5	Gastric
	<5.0	6–10	Any
	5.1–10	≤5	Gastric
High	Any	Any	Tumor rupture
	>10	Any	Any
	>5.0	>5	Any
	2.1–5.0	>5	Any
	5.1–10	≤5	Nongastric Nongastric

SECTION F: SMALL INTESTINE

Chapter 48

Anatomy and Physiology of the Small Intestine

E. Ramsay Camp, Kevin F. Staveley-O'Carroll, Niraj J. Gusani, Jussuf T. Kaifi, and Eric T. Kimchi

Key Points

- 1 The normal adult anatomy of the small intestine is the result of a complex cascade of embryologic events which result in 270 degrees of total rotation of the bowel around its axis. A failure of these precise steps produces a spectrum of anatomical variants which are grouped together as malrotation of the intestinal tract.
 - 2 There is no clear anatomic boundary between the jejunum and ileum. The proximal two-fifths of the small intestine distal to the ligament of Treitz have been arbitrarily defined as *jejunum* and the distal three-fifths as *ileum*.
 - 3 The enteric nervous system contains two major plexuses:
 - a. the myenteric (Auerbach) plexus, located between the longitudinal and circular muscle layers
 - b. the submucosal (Meissner) plexus
 - 4 The small intestine is the largest endocrine organ in the human body. The secretion of numerous hormones and neurotransmitters are specific to distinct anatomic zones within the small intestine.
 - 5 The coordinated movement of the gastrointestinal tract is necessary for the proper digestion of food. Well-timed contraction and relaxation patterns are initiated in gastrointestinal nervous system causing coordinated electrical activity and muscular movements.
 - 6 The lumen of the gastrointestinal tract is connected to the outside environment and comes in direct contact with many potentially pathogenic microorganisms. Consequently, the small intestine needs a complex defense mechanism to battle against these exposures in different ways.
 - 7 The small intestine reabsorbs nearly 80% of the fluid that passes through it. This dynamic process is accomplished by a rapid bidirectional movement of fluid in the intestinal lumen. This ebb and flow of fluid in the intestinal lumen is critical in maintaining normal homeostasis. Minor changes in intestinal permeability or rate of flow of the intestinal contents can result in net secretion and diarrheal states.
 - 8 While the exact mechanisms of many of the interactions between the gut microflora and the small intestinal microenvironment are still speculative, it has become evident that a symbiotic environment is present which, at least in part, is responsible for proper homeostasis of the small intestine.
-

The small intestine's intrinsic design serves to provide a maximum amount of surface area for absorption of nutrients, water, and electrolytes. Specialized areas provide neurohormonal stimulation to the digestive tract. Its structure and vast surface area also provide an important physical barrier to potential pathogens and certain areas are critical in immune surveillance.

GROSS ANATOMY AND EMBRYOLOGY

1 The small intestine spans from the pylorus to the ileocecal valve, and includes three distinct regions: the duodenum, the jejunum, and the ileum. These areas combined measure approximately 200 to 300 cm in a newborn and 5 to 7 m in an adult; comprising nearly 62% of the entire length of the alimentary tract. The gastrointestinal tract is formed from the endodermal layer of the developing embryo. The small intestine is derived from the distal foregut (proximal duodenum), midgut, and the adjacent splanchnic mesenchyme. Epithelium and glands develop from the embryonic endoderm, while connective tissue, muscle, and serosa develop from the mesoderm. During the 5th and 6th weeks of development, the duodenal lumen is temporarily obliterated due to proliferation of its mucosal lining.

During the subsequent weeks, luminal vacuolization and degeneration of some of the proliferating cells result in recanalization of the duodenal lumen. From the 4th to the 10th week of development, a large portion of the midgut is herniated through the umbilicus. This may be due to the rapid growth of the intestinal tract at this time in relation to the abdominal cavity. At approximately 8 weeks of gestation, the midgut begins to rotate in a counterclockwise manner 90 degrees around the axis of the mesenteric vasculature. The extra-abdominal portion of the gut returns to the abdominal cavity approximately 2 weeks later. Around this time point an additional 180-degree rotation occurs. These two rotations provide 270 degrees of total rotation and result in the typical anatomy that is found in humans. A failure of these precise steps produces a spectrum of anatomical variants which are grouped together as malrotation of the intestinal tract.¹

DUODENUM

The duodenum comprises the first portion of the small intestine and plays an important role in connecting the foregut organs to the midgut. It anatomically begins at the duodenal bulb which is immediately distal to the pylorus and terminates at the ligament of Treitz, where it joins the jejunum. The duodenum is approximately 20 to 30 cm in length and is divided into four distinct areas.

The first portion of the duodenum is approximately 5 cm in length and is referred to as the bulb or cap. This area is directly attached to the pylorus and extends laterally and cephalad. It serves as an attachment for the hepatoduodenal ligament and traverses over the common bile duct, portal vein, pancreatic head, and the gastroduodenal artery. The mucosal surface of the duodenal bulb is smooth until its junction with the second portion of the duodenum, where the concentric Kerckring folds begin. This portion of the duodenum is prone to ulceration, with approximately 90% of duodenal ulcers occurring here. Unfortunately, due to its anatomic positioning, these ulcers may erode into the gastroduodenal artery which lies directly posterior, causing potentially life-threatening bleeding.

The second portion of the duodenum (descending duodenum) extends from the origin of the Kerckring folds to the beginning of the transverse duodenum and travels over the right renal vasculature, the medial aspect of Gerota fascia, the inferior vena cava, and to the right of the L1 and L2 vertebra. It is approximately 10 cm in length and 3 to 5 cm in diameter. The Kerckring folds (plicae circulares) are concentric mucosal folds which are 1 to 2 mm thick and 2 to 4 mm high and are separated by 2 to 4 mm of smooth, flat mucosa. This portion of the duodenum serves as an entry point for pancreatic and biliary secretions into the gastrointestinal tract. This is typically through the major papilla (ampulla of Vater), which is a valvular structure arising in the midportion of the descending duodenum, approximately 7 to 10 cm from the pylorus. Through this point, the confluence of the common bile duct and the main pancreatic duct (duct of Wirsung) join the duodenum. The valvular function of the papilla is regulated through the muscular sphincter of Oddi. The minor pancreatic duct (duct of Santorini) enters through the minor papilla proximal to the ampulla of Vater in 50% to 60% of patients and endoscopically appears as a 1- to 3-mm polypoid structure.

The second portion of the duodenum is important surgically as it represents the entry of the duodenum into the retroperitoneum. Surgical evaluation of this part of the duodenum requires mobilization from its posterior and lateral attachments, described as a Kocher maneuver. This allows for further evaluation of the duodenum, pancreatic head, and bile duct.

The third (transverse) and fourth (ascending) portions of the duodenum complete the duodenal sweep. The third portion of the duodenum is about 10 cm in length and courses transversely from right to left, crossing the midline anterior to the spine, aorta, and inferior vena cava. This portion is closely attached to the uncinate process of the pancreas. The superior mesenteric artery (SMA) and vein (SMV) course anterior to the third portion of the duodenum to provide blood supply to the gut. The transition between the third and fourth portions of the duodenum is marked by the passage of the SMA in front of the duodenum. The SMA forms an acute angle as it originates from the aorta. An abnormally narrow angle can result in obstruction of the duodenum at this location (SMA syndrome). The fourth portion of the duodenum is approximately 5-cm long and courses upward and obliquely to reach the ligament of Treitz, marking the end of the duodenum and the return of the small bowel to the peritoneal cavity.

Figure 48-1. Arterial blood supply to the duodenum.

Following its embryologic origins, the vascular supply to the duodenum arises from branches of the celiac trunk for the foregut portion, whereas the distal (midgut origin) duodenum is supplied by branches of the SMA (Fig. 48-1). Venous drainage includes a series of pancreaticoduodenal veins which drain into the SMV–portal vein system. Lymphatic drainage follows the vascular supply with drainage to the pancreaticoduodenal nodes. From here, lymph drains superiorly to the hepatic nodes or inferiorly to the superior mesenteric nodes.

JEJUNUM AND ILEUM

2 Distal to the ligament of Treitz, the jejunum and ileum form the remainder of the small intestine. The boundary between the two is arbitrarily determined such that 40% of the intraperitoneal small intestine comprises jejunum and 60% comprises ileum. This portion of the bowel is suspended within the peritoneal cavity by a thin, broad-based mesentery that is attached to the posterior abdominal wall. The jejunum and ileum are freely mobile within the peritoneal cavity. The jejunum is the widest portion of the small intestine, whose caliber progressively decreases as it approaches the ileocecal valve. The mucosa of the jejunum has a thick lining and is characterized by prominent plicae circulares that become shorter and less frequent in the ileum. The total length of jejunum and ileum varies, but is usually between 5 and 7 m in length. The small intestine terminates in the right lower quadrant at the ileocecal valve. The ileocecal valve exhibits motor characteristics separate from the terminal ileum and colon, postulated to prevent reflux of fecal material from the colon into the small intestine.²

The arterial blood supply of the jejunum and the ileum arises from the SMA. The main vascular branches form arcades within the mesentery. The vasa recta, intestinal arterial branches, enter into the intestinal wall without anastomosing. The vasa recta of the jejunum are straight and long, in contrast to the vasa recta of the ileum, which are shorter with greater arborization (Fig. 48-2). The venous and lymphatic drainage follow the arterial supply. The main venous outflow is through the SMV which, along with the splenic vein, becomes the portal vein.

Figure 48-2. The superior mesenteric artery supplies bloodflow into the small intestinal arteries (vasa recta) which branch within the mesentery. In the jejunum (A), the vasa recta are straight and long, this is in contrast to the vasa recta within the ileum (B), which are shorter with greater arborization.

MICROSCOPIC ANATOMY

General Considerations

3 The wall of the small intestine is composed of four distinct layers—mucosa, submucosa, muscle, and serosa. The role of the mucosa is absorption and secretion. The luminal mucosal surface forms circular folds known as plica circularis or valvulae conniventes in all segments of the small intestine distal to the first portion of the duodenum. The submucosa contains an elaborate network of blood vessels, lymphatics, and nerves. The muscular portion of the wall includes outer longitudinal and inner circular muscle layers. Between the muscle layers lies the myenteric (Auerbach) plexus. The muscular layers are responsible for coordinating peristaltic movements. The outermost layer, the serosa, is composed of a thin layer of mesothelial cells overlying loose connective tissue. The serosa covers only the anterior surface of the retroperitoneal segments of small bowel, but it completely covers the portions of small bowel that are invested with mesentery.

Mucosa

The mucosa lines the luminal surface of the small intestine. It consists of three layers: epithelial cells, lamina propria, and a narrow layer of smooth muscle, the muscularis mucosae. The basic structural unit of the mucosa is the crypt and villus. Villi are finger-like projections of mucosa 0.5 to 1 mm high extending into the intestinal lumen that have a columnar epithelial surface and a cellular connective tissue core of lamina propria. Each villus contains a central lacteal (lymphatic), and a vascular network consisting of a small artery, vein, and capillaries. Ninety percent of the cells of the villi are columnar epithelial cells responsible for absorption and secretion. These cells are 22 to 25 μm high with basally located nuclei. The apices of these cells have microvilli, produced by numerous folds in the apical membrane, which account for the brush border appearance. Microvilli are approximately 1 μm long and 0.08 μm wide. Their surface is coated by glycoproteins rooted in the cell membrane. These glycoprotein filaments are referred to as the glycocalyx and are essential for digestion and absorption.³ The lateral membranes of neighboring enterocytes are connected by tight junctions, an apparent fusion of adjoining plasma membranes just below the level of the brush border. Movement of ions and water can occur by

either a transmembrane or a paracellular route through tight junctions, which behave as selective pores.

Between the villi lie the crypts of Lieberkühn. Stem cells within the crypts of Lieberkühn are the source of the four major types of differentiated cells: the absorptive enterocyte, goblet cells, enteroendocrine cells, and Paneth cells. Absorptive enterocytes differentiate as they migrate from the crypt compartment up toward the tip of the intestinal villus. Cells then undergo apoptosis and are shed into the intestinal lumen. Most of the intestinal lining is renewed over a period of approximately 5 days. Despite the rapid rate of cellular turnover, intestinal epithelial cells exhibit complex patterns of gene expression that vary according to their location on the two main spatial axes of the gut, the vertical (crypt-villus) and horizontal (proximal to distal) axes. For example, cells destined to become enterocytes do not begin to express a variety of genes important in digestion and absorption until the cells have migrated out of the crypt and up the villus. In addition, many epithelial cell genes are selectively expressed in the proximal small intestine, whereas other genes are specifically expressed only in the ileum.⁴

Several other cell types are present in the mucosa. Mucus-secreting goblet cells are present in both the crypts and villi. Goblet cells have a narrow base containing the nucleus and a wide apical membrane with a large number of granules containing mucin. Mucin is secreted in a merocrine fashion by the goblet cell and functions as a lubricant and has a cytoprotective function.⁵

Paneth cells are pyramidal cells that reside in the crypt base. They contain large eosinophilic secretory granules located at their apical surface. It is thought that Paneth cells play a role in host defense based on their abundant expression of lysozyme and defensins, a family of small peptides that are also found in human neutrophils and exhibit microbicidal activity toward many different bacterial organisms in vitro. However, examination of the role of Paneth cells in the small intestine by lineage ablation in transgenic mice revealed no alteration in host defense mechanisms, thus the actual function of Paneth cells are yet to be delineated.⁶

Enteroendocrine (also referred to as *amine precursor uptake and decarboxylation*, or *APUD*) cells may reside in either the crypts or the villi, depending on the particular neuroendocrine substance they produce. Specific areas of the small intestine have higher concentrations of specific neuroendocrine substances than other areas. These cells do not contact the intestinal lumen, unlike exocrine cells, and their secretory granules are located below the nucleus near the basement membrane. This suggests that these cells secrete their contents into the circulation rather than into the intestinal lumen.

Submucosa

The submucosa is a dense connective tissue layer with a rich network of blood vessels, nerves, and lymphatics. The submucosa contains Meissner plexus and is the strongest layer of the intestinal wall. Brunner glands are found in the submucosa of the duodenum and secrete mucus and bicarbonate into the intestinal lumen. These secretions aid in the neutralization of the gastric acid load which enters the duodenum. Peyer patches are localized collections of lymphoid follicles that are most prominent in the submucosa of the ileum. These are typically 8 to 10 mm in diameter and are most abundant early in life, gradually disappearing with age.

Physiology

4 The small intestine plays important physiologic roles in motility, blood flow, growth, digestion, absorption, immune function, and endocrine secretion. In fact, the small intestine is the largest endocrine organ in the human body.⁷ The secretion of numerous hormones and neurotransmitters are specific to distinct anatomic zones within the small intestine (Fig. 48-3). There is no specific cell mass which produces these hormones, but rather individual cells scattered along the gastrointestinal tract.

Gastrin is a peptide produced in the gastric antrum and in the duodenum by the G cells and secreted into the circulation in response to gastric distension, vagal stimulation, amino acids, and hypercalcemia. Gastrin exists in three functional forms (G-34, G-17, and G-14). Its release is inhibited by low intraluminal pH, somatostatin, secretin, gastric inhibitory peptide (GIP), vasoactive intestinal peptide (VIP), glucagon, and calcitonin. Gastrin binds to CCK2/gastrin receptors on ECL cells causing a release of histamine which in turn stimulates the parietal cells in a paracrine fashion. Gastrin also causes an increase in the gastric blood flow and the release of pepsinogen by the chief cells and pancreatic enzymes from the pancreatic centroacinar cells.

Figure 48-3. Distribution of peptide hormones in the gastrointestinal tract.

Cholecystokinin (CCK) is produced in the proximal two-thirds of the small intestine by the I cells and released into the gut lumen. It has 4 main forms (CCK-58, CCK-39, CCK-33, and CCK-8). It shares the final five amino acids adjacent to the C-terminus with gastrin, and this accounts for its hormonal activity. Stimulation of I cells by amino or fatty acids causes release of CCK, this in turn stimulates contraction and emptying of the gallbladder, increases bile flow, causes relaxation of the sphincter of Oddi, and stimulates pancreatic enzyme secretion. CCK also has trophic effects on the small intestinal mucosa and pancreas.

Secretin, discovered as the first gastrointestinal hormone in 1902, is a 27 amino acid peptide produced by the S cells of the duodenum and jejunum. Secretin is released into the circulation and intestinal lumen in response to low intraluminal pH, fatty acids, and bile salts. Water and bicarbonate are secreted by the pancreas in response to secretin. Bicarbonate is also released from the biliary ductal epithelium and Brunner glands in response to secretin. In turn, pancreatic enzymes are released from the pancreas. The increased pH and the presence of pancreatic enzymes aid in the digestion of lipids. The increased pH also provides a negative feedback loop to inhibit further production of secretin. Secretin produces a paradoxical release of gastrin in patients with gastrinomas, but does not produce this effect on normal individuals.

Somatostatin is a peptide hormone consisting of 14 or 28 amino acids and is produced by D cells in the pancreatic islets, gastric antrum, and duodenum. Its primary role is inhibition of other gastrointestinal hormones and inhibition of pancreatic, biliary, and gastric secretion. In addition, somatostatin decreases splanchnic and portal blood flow. Somatostatin is stimulated by the presence of fat, proteins, acid, glucose, amino acids, and CCK. Octreotide, a long-acting synthetic somatostatin analog, is used in the treatment of variceal bleeding, hormone secreting neuroendocrine tumors, carcinoid syndrome, and enterocutaneous and pancreatic fistulas.⁸

Gastrin-releasing peptide, the mammalian homolog of bombesin, is a 27 amino acid peptide which is produced by the small intestine and is released in response to vagal stimulation. It is a prostimulatory molecule which causes the release of most gastrointestinal hormones, with the exception of secretin. It also has a promotility effect and stimulates endothelial proliferation. Gastric inhibitory peptide or glucose-dependent insulintropic peptide (GIP) is a 42 amino acid peptide produced by the K cells of the duodenum and jejunum. It is released in response to glucose, fat, protein, and adrenergic stimulation. It stimulates secretion of insulin and inhibits gastric acid and pepsin production. Type 2 diabetics are

resistant to the effects of GIP.

Motilin is a 22 amino acid peptide produced by the enteroendocrine cells in the duodenum and jejunum. Release of motilin occurs during the interdigestive and fasting periods. Release may also be related to alkalization of the duodenum. Motilin's main function is to stimulate the migrating myoelectric complex. Motilin agonists such as erythromycin, are used clinically as stimulants of gastrointestinal motility.

VIP is a 28 amino acid peptide which is produced by gastrointestinal tract neurons. It serves as a neurotransmitter stimulating pancreatic exocrine and intestinal secretion. Conversely, it has an inhibitory effect on gastric acid secretion. VIP is a potent vasodilator and relaxant of smooth muscle.

Neurotensin is a 13 amino acid peptide that is produced by the N cells primarily in the ileum, but also in the proximal small intestine and colon in response to the presence of intraluminal fat. It stimulates pancreatic bicarbonate secretion and intestinal motility. Neurotensin also serves as a trophic factor on the small intestinal mucosa and inhibits gastric secretion.

Pancreatic glucagon and enteroglucagon are 29 and 37 amino acid peptides produced by the α -islet cells of the pancreas and the L cells of the small intestine, respectively. Pancreatic glucagon is released in response to low serum glucose and subsequently induces glycogenolysis, lipolysis, gluconeogenesis, and ketogenesis. Enteroglucagon is released in response to the presence of a mixed meal and inhibits gastric emptying and small bowel motility.

Motility

5 The coordination of movements of the gastrointestinal tract is necessary for the proper digestion of food. Well-timed contraction and relaxation patterns are initiated in gastrointestinal nervous system causing coordinated electrical activity and muscular movements. This may be influenced by both internal and external factors. The small intestine has motor functions which are distinct from the other parts of the gastrointestinal tract. The intrinsic nerves (myenteric or Auerbach plexus) provide the basis for coordinating the circular and longitudinal smooth muscles of the small intestine. Extrinsic sympathetic (epinephrine) stimulation slows motility while parasympathetic (acetylcholine) stimulation increases motility.

The intrinsic electrical activity of the small intestine is based on the intestinal smooth muscle normal resting potential. This normally is -50 to -70 mV and is maintained by Na^+ - K^+ -ATPase activity.⁹ The resting potential varies by 5 to 15 mV and results in a phasic depolarization which is referred to as slow waves, basic electrical rhythm, or pacemaker potential. These depolarizations occur at regular intervals of approximately 11 to 13 times per minute in the duodenum and decrease to 8 to 10 times in the ileum, but do not directly lead to muscular contractions. The electrical activity is coupled to muscular contraction at the level of gap junctions, which are low resistance cell-to-cell connections. These gap junctions become less regular in the midjejunum and in the distal small intestine. This causes slowing of the frequency of contractions distally, allowing for absorption of more slowly digested intestinal contents, including fats and bile salts.

Spike potentials represent a second mode of electrical stimulation of the small intestine. Spike potentials result in rapid depolarization of the membrane potential. Repeated bursts of spike potentials cause a short area of contraction. In contrast to the always present slow waves, spike potentials occur at discrete time intervals. The coordination of a slow wave and a spike potential leads to the initiation, duration, and frequency of rhythmic migratory small intestinal contractions.

During the interdigestive period between feeding, the small intestine follows a well-defined rhythmic pattern. This pattern consists of muscular contractions that migrate from the stomach or duodenum, continue on to the terminal ileum, and are regulated by the migrating motor complex (MMC). This pattern can be broken down into four distinct phases. Phase I is a period of relative quiescence; phase II is a period of accelerated irregular electrical spiking and muscular activity; phase III is a series of high-amplitude rapid electrical spikes corresponding to rhythmic gut contractions; and phase IV is a period of subsiding activity. This process occurs over a period of 90 to 120 minutes and progresses from the proximal small bowel and terminates in the ileum. Once the MMC reaches the terminal ileum, the process starts over again in the proximal small bowel. The circular muscles provide segmental contraction over a 1-cm length of small intestine. These contractions occur approximately 11 to 13 times per minute in the duodenum and decrease to 8 to 10 times in the ileum. This creates functional compartments where prolonged exposure to the mucosa and mixing of the intestinal chyme occurs, aiding the process of digestion and absorption. The circular muscles are also responsible for the peristaltic waves which propagate regularly at a rate of 1 to 2 cm/sec. These regular waves may be

interspersed with rushes of contractions followed by periods of no motor activity. This rate becomes progressively slower in the distal small intestine. These peristaltic movements serve as a method of propelling chyme through the length of the small intestine. The total transit time from the duodenum to the terminal ileum is approximately 220 minutes (+/-53 minutes).¹⁰ Serum motilin levels have been found to mirror the activity of the MMC. Exogenous motilin administration has been found to increase MMC activity.

During and immediately following times of feeding, the intestinal movements are not rhythmic, with complexes of peristaltic and antiperistaltic contractions. This is thought to be a disruption of the MMC from bolus feeding. This seemingly random pattern of movements allows for effective mixing of chyme. Hormonal changes are thought to play a role in this process. Physiologic doses of neurotensin, insulin, gastrin, and CCK cause an alteration in the MMC similar to bolus feeding. Visual and olfactory feeding cues can also cause a disruption of the MMC. The MMC is more significantly inhibited by fatty meals as opposed to protein or carbohydrate meals of similar caloric value. The intrinsic nervous plexus or Meissner plexus innervating the submucosa helps to regulate mucosal absorption and secretion, but has no control on motility.

IMMUNOLOGY

Principles of Gut Immunology

6 The lumen of the gastrointestinal tract is connected to the outside environment and comes in direct contact with many potentially pathogenic microorganisms. Lymphocytes, macrophages, polymorphic granulocytes and other cells that take part in immune response are distributed throughout the whole gut. The commensal microflora have many benefits to the host by supporting digestion and keeping the appropriate balance among different microbial species.¹¹ The immune system is highly effective at responding selectively to invading pathogens, yet on the other hand tolerating a much larger number of harmless food antigens and commensal organisms. Many bacteria, viruses and parasites are digested and enter the small intestine every day.¹² Consequently, the small intestine needs a complex defense mechanism to battle against these exposures in different ways.¹³

While the immune system in the small intestine is important for host defense, other mechanisms within the small intestine also participate in host defense. Proteolytic and lipolytic enzymes are produced in high concentrations by extraintestinal cells in the pancreas and degrade different pathogenic agents at an early phase of digestion. In addition, mucin is produced by the enterocytes which is cytoprotective and inhibits bacterial growth. The small intestine can actively increase peristalsis functions to mechanically get rid of pathogenic agents, which may be potentially dangerous to the gut. In addition, tight junctions between epithelial cells prevent penetration of bacteria in between cells. Potential pathogens vary greatly in size, from very small viruses that are nanometer in size, to parasites such as helminths that are macroscopically visible and quite large. To put this into the broader picture of evolution, a large range of defense mechanisms is essential for survival of each individual.

The primary cellular barrier in the gut that prevents antigens from encountering the immune system is the single layer of gut epithelium. The total surface area of the small intestine is 400 m², due not only to intestinal length but also due to the formation of millions of villi in the small bowel which contribute significantly to the overall surface area.¹⁴ In the upper small intestine, the bulk of antigen exposure comes from the diet, whereas in the ileum and colon, the additional antigenic load of an abundant and highly complex commensal microflora is prevalent. The epithelial cells of the gut mucosa have developed features that make the intestinal epithelium an active immunologic as well as anatomic barrier. For example, these nonclassical immune cells express major histocompatibility complex (MHC) class I and II molecules, consistent with their ability to participate in adaptive immune recognition of pathogenic bacteria. Small intestinal epithelial cells also express toll-like receptors on their apical surface that enables them to detect bacterial products and to initiate an innate immune response. Antigen-presenting dendritic cells (DCs) also send processes between gut epithelial cells without disturbing tight junction integrity and sample commensal and pathogenic gut bacteria.^{15,16} The gut epithelial barrier therefore represents a highly flexible structure that limits antigens from entering the systemic body.

The gut-associated immune system represents one of the largest immunologic compartments in the body. Lymphoid tissue in the gastrointestinal tract is a major part of the whole-body immune system

and consists of both aggregated (lymphoid follicles, Peyer patches) and nonaggregated (luminal, intraepithelial and in lamina propria) immune cells. Under physiologic circumstances, oral administration of protein antigens induces systemic unresponsiveness when the same antigen is given parenterally (a phenomenon known as oral tolerance). In animal models, oral tolerance appears to be a specific consequence of the immune environment in the gut, which favors the generation of regulatory T cells.

Nonaggregated and Aggregated Lymphoid Tissue

The gut epithelium and its mucous layer form a major barrier to trap pathogens which are then eliminated when the gut epithelium is shed and replaced by new cells deriving from stem cells in the crypts. Several different cell types face antigenic exposure present in the intestinal lumen and include the epithelium, neutrophils, lymphocytes, and macrophages. These luminal cells represent an initial effector mechanism in the first front directed toward an antigenic exposure. In addition, there are also immigrated intraepithelial lymphocytes, which are found in between epithelial cells beneath the tight junctions. Local defense depends in part on these T lymphocytes that are nestled among gut epithelial cells. These T cells modulate homeostasis of the gut epithelium through local production of cytokines and have cytolytic effects. In fact, the number of intraepithelial lymphocytes can increase dramatically in response to inflammation or infection. After exposure to antigens, these cells reenter the circulation to initiate a systemic immune response. The lamina propria contains nonaggregated, diffusely distributed lymphoid tissue, including different types of immune cells (Fig. 48-4). B cells in the lamina propria undergo cytokine-induced differentiation to become active producers of immunoglobulin A (IgA) that is secreted into the gut lumen. T cells in the lamina propria may have a different role in a helper-inducer function for immunoglobulin production rather than a cytolytic function. Mast cells and eosinophils are also present in the lamina propria in small numbers. They exhibit an important role in allergic and hypersensitivity reactions as well as defense against parasites. Parasites including worms are recognized and tagged using the monovalent immunoglobulin E (IgE) which is mostly bound to host cell surfaces. Actual parasite killing is depending on toxic proteins secreted by eosinophils.

There are also large aggregates of lymphoid tissue found in the small intestine. These so-called Peyer patches are localized collections of lymphoid follicles that are most prominent and macroscopically visible in the submucosa of the ileum. Peyer patches are most prominent in children and gradually disappear with age. Along with the nonaggregated immune system, the enormous quantity and diversity of antigens present within the gut are also processed via Peyer patches in the lamina propria and the mucosa-associated lymphoid tissue (MALT), which in total contains about 70% of the body's lymphoid cells. Another often used term to describe the immune system within the small intestine is gut-associated lymphoid tissue (GALT). Peyer patches do not have any villi, and so-called microfold (M) cells concentrated within the epithelium allow the selective uptake of food antigens and microorganisms (Fig. 48-5). M cells are specific cells in the intestinal epithelium over lymphoid follicles that endocytose antigens. M cells transport them into the underlying tissue, where they are taken up by local DCs and macrophages.¹⁷ DCs and macrophages that receive antigens from M cells present them to T cells in the GALT, leading ultimately to appearance of IgA-secreting plasma cells in the mucosa. B-lymphocyte precursors proliferate in germinal centers within the Peyer patches. DCs below the epithelium can also take up luminal antigens by pushing pseudopods up between epithelial cells.

Immunoglobulin Secretion

At an early level of exposure at the gut epithelium, M cells take up antigen and transport it transcellularly using an endocytic mechanism into the underlying lymphoid tissues of Peyer patches. Lymphocyte activation ensues, and these activated lymphocytes migrate into afferent lymphatics, pass through mesenteric lymph nodes, and enter the circulation through the thoracic duct. During this process, the lymphocytes mature into B and T lymphoblasts with an enriched population of IgA-producing B cells.¹⁸ Passage of viable bacteria from the intact gastrointestinal tract to the mesenteric lymph node and beyond has been termed bacterial translocation, possibly explaining septic complications and multiple organ failure in peritonitis, burn and trauma patients. The immunogenic integrity of the mucosa is significantly damaged by systemic injury of different kinds. A major protective mechanism of the intestinal immune system is synthesis and secretion of IgA. In the intestine, IgA exists as a dimer that is linked with two additional molecules – the J chain – linking two IgA molecules, and the polymeric immunoglobulin receptor, which transports the IgA complex across the cell and allows release of the complex, termed *secretory component*, into the intestinal lumen. The

transmembranous immunoglobulin receptor is produced by the intestinal epithelial cell. It is thought that the secretory component may prevent proteolytic degradation of the IgA molecule and may stabilize the structure of the polymeric IgA complex in an environment containing numerous proteolytic enzymes and bacteria that would otherwise rapidly degrade it. Unlike IgG and IgM, IgA does not activate complement and does not promote cell-mediated opsonization. The major function of secretory IgA in host defense is protection against bacteria, viruses, and luminal antigens. Secretory IgA inhibits the adherence of bacteria to epithelial cells. It is well known that a breast-feeding mother transfers secretory IgA to her nursing infant, protecting the infant from bacteria and viruses that were originally present in the mother's gastrointestinal tract.

Figure 48-4. Small intestinal villus with associated immunologic cells.

DIGESTION AND ABSORPTION

Absorption of Water and Electrolytes

7 An average person consumes approximately 1 to 1.5 L of water per day. An additional 5 to 10 L is secreted by the gastrointestinal tract: 1 to 2 L of saliva, 2 to 3 L of gastric secretions, 0.5 L of biliary secretions, 1 to 2 L of pancreatic juice, and 1 L of intestinal secretions. The small intestine reabsorbs nearly 80% of the fluid that passes through it. This dynamic process is accomplished by a rapid bidirectional movement of fluid in the intestinal lumen. This ebb and flow of fluid in the intestinal lumen is critical in maintaining normal homeostasis. Minor changes in intestinal permeability or rate of flow of the intestinal contents can result in net secretion and diarrheal states.

Figure 48-5. Epithelial anatomy in the area of Peyer patches.

The tonicity of the intraluminal contents determines the overall net movement of water. In general, after a meal is consumed, the addition of large amounts of saliva, gastric juice, and hypotonic chyme enters the proximal small intestine. Acid gastric contents are neutralized by the secretion of bicarbonate, creating NaCl and water, and decreasing the osmotic pressure. The jejunum is effective at passively reabsorbing water in a paracellular fashion due to its relatively large intercellular pores. As the chyme travels through the length of the small intestine, the intercellular channels become more tightly arranged and the movement of water becomes dependent on the active transport of solutes into the paracellular spaces. A total of 6 to 11 L of water enters the duodenum every day, of this, less than 1 L enters the colon.

Sodium absorption occurs through several different processes. Simple electrogenic absorption, nonelectrolyte-stimulated absorption, and electroneutral absorption are reliant on the $\text{Na}^+\text{-K}^+\text{-ATPase}$ pump on the basolateral membrane of the cell. This pump utilizes the hydrolysis of ATP to provide the necessary energy to move 3 Na^+ ions out of the cell while transporting 2 K^+ ions into the cell against an electrical gradient. This process maintains a negatively charged low Na^+ intracellular environment, allowing for several mechanisms of absorption at the apical membrane. Simple electrogenic absorption of sodium is the process of an influx of Na^+ ions from the sodium-rich intestinal lumen into the negatively charged low-sodium intracellular environment. This process is indirectly energy dependent, as it relies on the function of the $\text{Na}^+\text{-K}^+\text{-ATPase}$ pump on the basolateral membrane to maintain the low sodium environment and the negative intracellular charge. This process can be inhibited by ouabain, a $\text{Na}^+\text{-K}^+\text{-ATPase}$ inhibitor.¹⁹

Nonelectrolyte-stimulated sodium absorption occurs when sodium is coupled with an organic solute, such as glucose, amino acids, dipeptides, tripeptides, and bile acids. Sodium is preferentially transported down its electrochemical gradient which is created by the $\text{Na}^+\text{-K}^+\text{-ATPase}$ pump on the basolateral membrane of the cell, providing the necessary energy to transport the organic solute against its gradient (Fig. 48-6A). Electroneutral absorption of sodium chloride occurs through a process which couples two neutral ion countertransport mechanisms. Na^+ is exchanged for H^+ and Cl^- is exchanged for HCO_3^- , resulting in no net change in intracellular charge. This process provides an influx of NaCl in exchange for H^+ HCO_3^- efflux. This electroneutral transfer of ions allows for intracellular pH regulation and for sodium and chloride transport (Fig. 48-6B).

Figure 48-6. Mechanisms of sodium absorption in the small intestine: solute-coupled Na^+ absorption (A) and electroneutral NaCl absorption (B).

While the majority of chloride is absorbed by electroneutral transfer, chloride is also absorbed by passive diffusion in a paracellular fashion. This is due to the slightly positive interstitium when compared to the gut lumen, allowing the negatively charged chloride ions to be absorbed. An additional important source of chloride transport involves the reabsorption of chloride ions contained within gastric hydrochloric acid secretions. Chloride is a major determinant of the regulation of fluid secretion into the small intestine and in intestinal hydration.²⁰

Bicarbonate absorption occurs primarily in the jejunum and requires the formation of carbon dioxide in the intestinal lumen from HCO_3^- and H^+ . This creates an increase in the partial pressure of carbon

dioxide in the intestinal lumen. Carbon dioxide subsequently diffuses back into the enterocyte and is enzymatically cleaved into H^+ and HCO_3^- by the action of carbonic anhydrase. HCO_3^- diffuses into the interstitium and H^+ is resecreted in exchange for other cations, predominantly Na^+ . In the duodenum and ileum, HCO_3^- is secreted in exchange for Cl^- . This efflux of HCO_3^- provides a mechanism to neutralize gastric acid entering into the duodenum. HCO_3^- secretion in the ileum most likely helps maintain acid–base equilibrium, although this process is not well understood.²¹

Approximately 90 mEq/d of potassium is ingested in a normal diet of which 90% is absorbed. An equal amount of potassium is excreted in the urine as is absorbed in the intestine, allowing maintenance of potassium homeostasis. The majority of absorption occurs in the small intestine mainly through passive mechanisms.²² This process is thought to occur through intercellular pores or through an H^+ - K^+ exchange pathway facilitated by the intracellular electrochemical gradient which is created predominantly by the basolateral ATPase pump. Intracellular K^+ then diffuses across the basolateral membrane by a K^+ channel or carrier.

Mineral Absorption

Mineral absorption is necessary for the proper form and function of the human body. These inorganic elements are responsible for approximately 4% to 6% of a person's mass. Calcium accounts for approximately 50% of this mass, phosphate provides an additional 25%, and a variety of other minerals constitute the remaining 25%. Many of these minerals are best absorbed in their ionized forms, which is aided by the presence of hydrochloric acid in the gastric lumen. Calcium, phosphate, magnesium, sulfur, sodium, chloride, and potassium are considered macrominerals, with daily requirements exceeding 100 mg/d. Microminerals (trace minerals) include iron, zinc, copper, manganese, iodine, selenium, fluoride, molybdenum, chromium, and cobalt with daily requirements of less than 15 mg/d.

Approximately 1 g of calcium is consumed per day, mainly from dairy products. Once in its ionized form, calcium is primarily absorbed in the duodenum, although this process occurs throughout the length of the small intestine. When calcium is present intraluminally at low levels, it is transported across the apical membrane of the enterocyte by carrier-mediated facilitated diffusion. Once calcium is in the cytoplasm, it is bound to calcium-binding proteins and delivered to the basal membrane. Calcium is then transferred into the interstitium by a Ca^{2+} -ATPase pump. This process is indirectly regulated by parathyroid hormone (PTH). PTH in low-calcium states promotes conversion of vitamin D to its active form 1,25-(OH)₂ vitamin D. This activated form of Vitamin D causes an increase in the expression of both calcium-binding proteins and Ca^{2+} -ATPase, causing an increase in the absorption of calcium by the small intestine.^{23,24} When intraluminal calcium is in excess of its capacity to be actively transferred by the apical membrane's carrier-mediated mechanism, passive paracellular calcium absorption occurs in the distal small intestine.

Absorbable dietary sources of iron are typically either contained within a protein, such as heme, or as a ferrous (Fe^{2+}) ion. Iron-containing proteins are usually from ingested meats, whereas ferrous forms are typically present in vegetables, grains, and fruits. Vitamin C (ascorbic acid) increases iron absorption by reducing the ferric (Fe^{3+}) ion into the more soluble ferrous state. Absorption of iron is facilitated by carrier-mediated translocation across the apical membrane of the enterocyte in the duodenum and proximal jejunum. Once in the cytoplasm, the ferrous ion is released by enzymatic cleavage. Ferrous ions may be stored intracellularly by ferritin or transported into the circulation by transferrin. The process of iron absorption is regulated in the enterocyte by hypoxia-inducible factor signaling and iron-regulatory proteins. Systemically, the central iron regulatory hormone is hepatic hepcidin. Hepatic hepcidin regulates iron absorption and mobilization from systemic stores by inhibiting ferroportin, a cellular iron exporter.²⁵

Carbohydrate Digestion and Absorption

Carbohydrates are a staple in many diets and provide a major source of daily caloric intake. In Western diets, 400 g of carbohydrates are consumed by the average adult daily, providing 1,600 kcal (4 kcal/g of carbohydrate). Carbohydrates are present in three main digestible forms: complex starches, disaccharides, and simple sugars. Complex starches account for approximately 60% of daily carbohydrate intake. The most common form is amylopectin which consists of glucose linked in a linear fashion with $\alpha(1,4)$ -glycosidic bonds with branch points consisting of $\alpha(1,6)$ -glycosidic linkages occurring after approximately every 20 to 26 glucose moieties. Amylose is a long linear grouping of glucose molecules connected with $\alpha(1,4)$ -glycosidic bonds without branch points. Disaccharides, mainly sucrose and lactose, are the next most common source of dietary carbohydrates, representing nearly a

third of daily intake. Sucrose disaccharides are comprised of glucose–fructose dimers, whereas lactose disaccharides consist of glucose–galactose dimers.

The complex starches, amylopectin and amylose, are digested with the aid of salivary and pancreatic amylase. Salivary amylase contributes a small amount to this process as it is inactivated by gastric acid, leaving the remainder of this process to be completed by pancreatic amylase. This process yields maltose, which are glucose dimers with $\alpha(1,4)$ -glycosidic bonds, and maltotriose, which are glucose trimers with $\alpha(1,4)$ -glycosidic bonds. In addition, α -dextrins are produced with an average of 6 glucose moieties with $\alpha(1,4)$ -glycosidic bonds and side branches linked by $\alpha(1,6)$ -glycosidic bonds. This digestive process is usually completed before the carbohydrate bolus leaves the duodenum. These small oligosaccharides along with ingested disaccharides, typically sucrose and lactose, are then further digested by the brush border saccharidases in the jejunum.

The brush border of the small bowel contains specific enzymes which through catalytic reactions hydrolyze these oligo- and disaccharides into their component monosaccharide moieties, such as glucose, galactose, and fructose. Once broken down into their basic subunits, these monosaccharides can be transported across the apical cell membrane. A sodium-dependent hexose transporter (SGLUT-1) is required for the transport of glucose and galactose as they utilize the same carrier mechanism. The cotransportation of these monosaccharides with sodium is dependent on the Na^+ - K^+ -ATPase pump on the basolateral membrane to maintain a sodium gradient allowing for this influx. Fructose is transported in a carrier mediated diffusion dependent manner by GLUT5 and does not require sodium as a cotransporter (Fig. 48-7). The movement of monosaccharides into the cellular cytoplasm provides an additional gradient by which water is absorbed by the enterocytes from the intestinal lumen. The monosaccharides are then transported across the basolateral membrane by GLUT2. This hexose transporter allows for the diffusion of all three monosaccharides into the extracellular space and ultimately into the portal blood flow. A small portion of these monosaccharides may be used by the enterocyte, but the majority is transported through the cell.

Nondigestible carbohydrates (dietary fiber) such as cellulose are thought to be an important part of a normal diet even though they do not provide dietary calories. Dietary fiber is present in grains, vegetables, and pulpy fruits. Dietary fiber helps decrease bowel transit time by absorbing water in the intestinal lumen. In addition, fiber can absorb organic materials such as lipids and bile salts and inorganic minerals such as zinc, calcium, and magnesium. These actions of fiber are thought to play a role in preventing carcinogenesis and in helping to maintain normal serum lipid profiles. Unfortunately, fiber is underrepresented in most Western diets.

Protein Digestion and Absorption

Protein consumption is essential to the daily diet. An average adult requires 0.75 g/kg of protein per day, although this requirement may be significantly increased during childhood, pregnancy, and times of significant illness. Protein provides an important caloric energy source as well as the essential building blocks for production of new proteins. A nearly equal amount of protein is ingested daily from dietary sources (70 to 100 g) as is provided by endogenous proteins (50 to 60 g of protein per day) in the small intestine from secreted enzymes, desquamated cells, and plasma protein leakage. Nearly 90% of this protein load is metabolized in a similar fashion to dietary proteins.

The initial digestion of protein begins with the activation of pepsinogen to pepsin in the acid environment of the stomach. Pepsin hydrolyzes protein into its component amino acids; however this action only represents a small part of overall protein digestion. The majority of protein digestion occurs in the small intestine by pancreatic peptidases and proteases. Pancreatic enzymes flow into the duodenum, initiating this phase of protein digestion. These pancreatic proteases are initially released as proenzymes (zymogens). These zymogens are inactive and require a further catalytic process to occur for their activation. This is initiated by the brush border enzyme enteropeptidase (enterokinase) in the duodenum. Endopeptidase cleaves trypsinogen into the active enzyme trypsin. Trypsin in turn activates the other zymogens into their active endopeptidases (trypsin, chymotrypsin, and elastase) which hydrolyze internal peptide bonds. Additional protein digestion is performed by exopeptidases (carboxypeptidase A and B) which are able to cleave amino acids from the C-terminal ends of proteins. Seventy percent of the process results in short oligopeptides of 2 to 6 amino acids and the remaining 30% produces single amino acids.

Figure 48-7. Digestion and absorption of carbohydrates.

Short oligopeptides are further digested by enzymes in the brush border of the small intestine or within the cell cytoplasm. Single amino acids, dipeptides, and tripeptides are able to diffuse through the apical membrane into the cytoplasm. Single amino acids are cotransported into the cytoplasm with sodium along an electrochemical gradient. This electrochemical gradient is maintained by the $\text{Na}^+\text{-K}^+\text{-ATPase}$ pump on the basolateral cell membrane. At least four separate transport mechanisms exist for the various electrochemical properties of amino acids which are transported (neutral, dibasic, acidic, and imino). Peptides greater than 3 amino acids in length are broken down into smaller peptides by enzymes in the brush border. The resultant dipeptides and tripeptides are then moved into the cytoplasm along with H^+ by a cotransporter PepT1 , where they are hydrolyzed by specific peptidase into their component amino acids. Transport of amino acids into the cytosol provides an osmotic gradient by which water is further absorbed from the intestinal lumen. A small portion of the processed amino acids are utilized by the enterocyte, and the vast majority is shuttled into the portal blood flow via amino acid transporters on the basolateral membrane.

Fat Digestion and Absorption

Forty percent of the average daily caloric intake (60 to 90 g) in a Western diet is in the form of fat. Ninety percent of these ingested fats are triglycerides, while the remainder is comprised of cholesterol, phospholipids, and fat-soluble vitamins. The initiation of lipid digestion occurs when CCK is stimulated by the presence of fatty acids on the duodenal mucosa. CCK in turn stimulates pancreatic secretion of lipase and its cofactor colipase. Lipase hydrolyzes triglycerides at the 1 and 3 positions of the glycerol backbone, yielding two fatty acids and a monoglyceride (a fatty acid esterified to glycerol). Cholesterol and fat-soluble vitamins are hydrolyzed by pancreatic cholesterol esterase and phospholipids by phospholipase A_2 . The products of lipolysis interact with bile salts to form water soluble micelles. Mixed micelles are 50 to 400 Å in diameter and are a combination of fatty acids, bile salts, and monoglycerides. The structure of a micelle is composed of an inward facing hydrophobic region and a hydrophilic region facing outward toward the aqueous environment of the intestinal lumen. Due to the hydrophobic core, cholesterol, phospholipids, and fat-soluble vitamins can reside within the micelle structure. Micelles are able to interact with the mucosal cells and empty their contents into the cytoplasm. This occurs by the process of dissolution of the micelles into the lipid bilayer of the mucosal cell. Once this is completed, the components of the micelle are ready to reform with new lipid components to repeat this process. There is no energy consumed directly in the transfer of lipids into the cell cytoplasm.

Once in the cytoplasm, long-chain fatty acids and β -monoglycerides are carried by cytosolic fatty acid-binding proteins to the smooth endoplasmic reticulum (SER). In the SER, resynthesis of triglycerides occurs. These triglycerides are further processed in the Golgi apparatus where a phospholipid and an apoprotein coat are added to form a chylomicron. Chylomicrons are 90% triglyceride; the remaining 10% is composed of phospholipid, cholesterol, and protein. These large

particles are 750 to 6,000 Å in diameter. Before exiting the Golgi apparatus, the chylomicrons are packaged into secretory vesicles. They exit the cell membrane by exocytosis and enter the central lacteal of the villus and the intestinal lymphatic system. In addition, enterocytes also produce smaller lipoprotein particles, very low density lipoproteins, which contain a higher cholesterol/triglyceride ratio and provide the major route of entry for dietary cholesterol into the lymphatic system.

Short chain fatty acids contain less than 8 carbon atoms and are water soluble. This allows these molecules to enter and exit the enterocyte by simple diffusion independent of bile micelles or chylomicrons. Medium chain triglycerides consist of 6 to 12 carbon atoms and can be absorbed by simple diffusion or through the previously mentioned process of transport of long chained fatty acids via the formation of bile micelles and chylomicrons. Both short and medium chain fatty acids may enter the portal circulation without entering into the lymphatics. The majority of dietary fat is processed and absorbed in the duodenum and upper jejunum.

Absorption of Bile Salts

Approximately 95% of the bile salts secreted into the intestine are reabsorbed and returned to the liver through the portal circulation. Once in the liver, these bile salts are reprocessed and secreted and stored in the gallbladder in preparation for the next meal. This process of recycling of bile salts is referred to as the enterohepatic circulation. This reabsorption occurs by both passive and active means. A small amount of bile salts are passively reabsorbed along the entire length of the small intestine. The majority of bile salts, however, are reabsorbed through an active Na⁺-dependent transport mechanism in the terminal ileum. Bile, which is not reabsorbed, passes into the colon where it is deconjugated by bacteria. This process increases the solubility of the bile and promotes further passive absorption. High concentrations of bile salts within the colon inhibit sodium and water reabsorption, resulting in diarrhea. Patients who have undergone resection of their ileum may suffer from diarrhea due to this process. These patients may be treated with the bile-binding resin, cholestyramine, to help alleviate their symptoms.

Vitamin Absorption

Fat-soluble vitamins (A, D, E, and K) are incorporated into micelles along with fats in order to pass into the enterocyte. These vitamins are then processed and packaged into chylomicrons so that they can exit into the lymphatic system. Water-soluble vitamins are absorbed in the jejunum and ileum through a variety of mechanisms. Vitamin C (ascorbic acid), biotin, and niacin are transported by Na⁺-dependent mechanisms. Folate, vitamin B₁ (thiamine), and vitamin B₂ (riboflavin) are absorbed by Na⁺-independent mechanisms and vitamin B₆ is absorbed by passive diffusion.²⁵

Vitamin B₁₂ (cobalamin) absorption is dependent on the presence of intrinsic factor, a glycoprotein produced by the gastric parietal cells. One molecule of intrinsic factor binds two molecules of cobalamin to form a complex which attaches to a specific membrane receptor in the terminal ileum. Unbound cobalamin cannot be absorbed. Cobalamin becomes unbound from its complex in the enterocyte and exits from the cell into the portal circulation with the aid of B₁₂-binding proteins called transcobalamins. Cobalamin is essential for DNA synthesis and a deficiency usually presents with megaloblastic anemia. Inability to absorb sufficient amounts of cobalamin may be due to lack of intrinsic factor after proximal or total gastrectomy, autoimmunity to gastric parietal cells or intrinsic factor, or atrophic gastritis. In addition, cobalamin-intrinsic factor complexes may fail to be absorbed due to distal ileal disease or resection, and cobalamin deficiency may occur from bacterial overgrowth due to bacterial overconsumption of cobalamin.

Small Intestinal Microbiota

8 The importance of the microbiota of the small intestine on metabolism and its impact on health and disease processes are increasingly being realized. The small intestine is not highly populated by bacteria due to its relatively inhospitable environment, which is comprised of a variety of antimicrobial proteins, immunoglobulins, and a low pH. Bacterial populations of the small intestine have been estimated at 10³/g in the duodenum to 10⁸/g in the distal ileum, but despite these relatively low populations there is evidence that there is interplay between the microbes and the intestinal lining that may directly affect intestinal health.²⁶ The role of microbes and bile acid metabolism is relatively well understood, but new findings about the regulation of bile acid conjugation are cited as possible factors in irritable bowel disease and inflammatory bowel disease.²⁷ Metabolism of fatty acids, dietary fiber, and amino acids

alter the production of microbial anti-inflammatory and proinflammatory factors and is thought to play an important role in mucosal integrity and translocation, as well as, hepatic function and may have a role in the pathogenesis of nonalcoholic fatty liver disease.^{28–32} While the exact mechanisms of many of the interactions between the gut microflora and the small intestinal microenvironment are still speculative, it has become evident that a symbiotic environment is present which, at least in part, is responsible for proper homeostasis of the small intestine.

Chapter 49

Ileus and Bowel Obstruction

David I. Soybel and Ariel P. Santos

Key Points

- 1 Peritoneal adhesions account for more than half of small bowel obstruction (SBO) cases.
 - 2 In simple obstruction the intestinal lumen is partially or completely occluded without compromise of intestinal blood flow. Simple obstructions may be complete, meaning that the lumen is totally occluded, or incomplete, meaning that the lumen is narrowed but permitting distal passage of some fluid and air. In strangulation obstruction, blood flow to the obstructed segment is compromised and tissue necrosis and gangrene are imminent.
 - 3 Four key symptoms that are associated with acute mechanical bowel obstruction include abdominal pain, vomiting, distention, and obstipation; abdominal pain out of proportion to physical findings should raise concern about rapidly evolving closed-loop obstruction and the need for urgent resuscitation and operation.
 - 4 Use of water-soluble contrast may be both diagnostic and therapeutic.
 - 5 Increasingly, computed tomography (CT) is the “go-to” imaging modality to detect and identify the likely site and source of obstruction.
 - 6 Conservative management consisting of intravenous hydration, nasogastric decompression, and restoration of electrolyte balance is a cornerstone of initial management of any patient suspected of having intestinal obstruction.
 - 7 Open exploratory laparotomy is the gold standard in treating unresolved SBO but laparoscopic management should be considered in select group of patients. Types of intestinal obstruction that are more likely to lead to strangulation and the need for urgent/emergent operation include closed-loop obstructions, obstruction that occurs without a prior history of operation, and obstructions that occur after laparoscopic procedures.
 - 8 Ileus denotes underlying alterations in motility of the gastrointestinal tract, leading to functional obstruction.
 - 9 Postoperative ileus (POI) can be differentiated from SBO with the use of contrast CT and enteroclysis imaging techniques.
 - 10 POI is often self-limiting; less frequent interventions are required for prolonged POI, if proper precautions have been taken during surgery.
-

INTRODUCTION AND HISTORICAL PERSPECTIVE

The purpose of this chapter is to provide an overview of the pathophysiology, natural history, diagnosis, and management of acute obstruction and ileus of the small and large intestines. The development of the modern approach to intestinal obstruction and ileus paralleled the development of techniques for safe abdominal surgery. Chief among these accomplishments were the discovery of safe general anesthetics, the popularization of aseptic methods in the operating rooms and management of wounds, and the development of techniques for intestinal resection, intestinal anastomosis, and colostomy. The foundations of the recognition and management of intestinal obstruction and ileus are attributed to Frederick Treves.¹⁻³ In 1884, he published a detailed discussion of the etiologies (including adhesions) and surgical management of mechanical intestinal obstruction.¹ Treves also distinguished mechanical from nonmechanical (i.e., paralytic) causes of intestinal distention, classifying the latter causes under the term *ileus*. From 1880 to 1925, proximal intestinal decompression was recognized to provide relief from the symptoms of mechanical obstruction or ileus.³ In 1933, Wangensteen and Paine reported the efficacy of gastrointestinal intubation in relieving symptoms of intestinal distention caused by intestinal obstruction or from the ileus that resulted from laparotomy.^{4,5} Subsequently, Wangensteen and Rea

provided experimental evidence that the source of gaseous distention in cases of obstruction or ileus was swallowed air.⁶ The value of intravenous fluid resuscitation in experimental models of intestinal obstruction was recognized as early as 1912⁷ and became a principle of care of the patients with intestinal obstruction in the late 1920s. By 1920, plain abdominal radiographs were used in diagnosis of intestinal obstruction.³ Thus, the principles of early diagnosis, rapid intravenous fluid resuscitation, gastrointestinal decompression, and early operation to avoid intestinal gangrene and peritonitis, were established well before the advent of antibiotic therapy, invasive hemodynamic monitoring, and parenteral nutrition.⁸ These early developments were most important in reducing morbidity and mortality of mechanical intestinal obstruction and ileus.⁹

MECHANICAL OBSTRUCTION OF THE INTESTINES

Terminology and Classification

The term *mechanical obstruction* means that luminal contents cannot pass through the gut tube because the lumen is blocked. This obstruction is in contrast with *neurogenic* or *functional* obstructions in which luminal contents are prevented from passing because of disturbances in gut motility that prevent coordinated peristalsis from one region of the gut to the next. This latter form of obstruction is commonly referred to as *ileus* in the small intestine and *pseudo-obstruction* in the large intestine. In *simple* obstruction the intestinal lumen is partially or completely occluded without compromise of intestinal blood flow. Simple obstructions may be *complete*, meaning that the lumen is totally occluded (Fig. 49-1), or *incomplete*, meaning that the lumen is narrowed but permitting distal passage of some fluid and air. In *strangulation* obstruction, blood flow to the obstructed segment is compromised and tissue necrosis and gangrene are imminent. Strangulation usually implies that the obstruction is complete, but some forms of partial obstruction can also be complicated by strangulation.

Figure 49-1. Schematic illustration of different forms of simple mechanical obstruction. Simple obstruction is most often due to adhesion (A), groin hernia (B), or neoplasm (C). The hernia can act as a tourniquet, causing a closed-loop obstruction and strangulation.

1 The various forms of mechanical intestinal obstruction can be classified according to different but overlapping schemes. Most commonly, obstruction is classified according to etiology. As detailed in [Table 49-1](#), distinctions are drawn between intraluminal obturators such as foreign bodies or gallstones, intramural lesions such as tumors or intussusceptions, and extrinsic or extramural lesions such as adhesions. Adhesions are the most common cause of intestinal obstruction, accounting for more than half of all cases. In order to highlight the pathophysiology, presentation, and natural history, however, it is useful to classify obstruction according to the location of the obstructing lesion. Proximal or “high” obstructions involve the pylorus, duodenum, and proximal jejunum. Intermediate levels of obstruction involve the intestine from the midjejunum to the midileum. Distal levels of obstruction arise in the distal ileum, ileocecal valve, and proximal colon whereas the most distant or “low” obstructions would arise in regions beyond the transverse colon. As shown in [Table 49-2](#), clinical symptoms and signs of obstruction (pain, vomiting, abdominal distention, and gas pattern on abdominal radiographs) vary with the level of obstruction.

It is also important to distinguish between *open-loop* and *closed-loop* obstructions. An open-loop obstruction occurs when intestinal flow is blocked but proximal decompression is possible through vomiting. A closed-loop obstruction occurs when inflow to the loop of bowel and outflow from the loop are both blocked. This obstruction permits gas and secretions to accumulate in the loop without a means of decompression, proximally or distally. Examples of closed-loop obstructions are torsion of a loop of small intestine around an adhesive band ([Fig. 49-2](#)), incarceration of the bowel in a hernia, volvulus of the cecum or colon, or development of an obstructing carcinoma of the colon with a competent ileocecal valve. The primary symptoms of a closed-loop obstruction of the small intestine are sudden, severe midabdominal pain and vomiting whereas symptoms of the large intestine are pain and sudden abdominal distention. This pain often occurs before associated findings of localized abdominal tenderness or involuntary guarding. When signs of peritoneal irritation or frank peritonitis develop, there is a high level of suspicion that the viability of the bowel is compromised.

Table 49-1 Classification of Adult Mechanical Intestinal Obstructions

Intraluminal	Intramural	Extrinsic
Foreign bodies Barium inspissation (colon) Bezoar	Congenital (rare in adult) Atresia, stricture or stenosis Web Intestinal duplication Meckel diverticulum	Adhesions Congenital: Ladd's or Meckel bands Postoperative Postinflammatory (after pelvic inflammatory disease)
Inspissated feces Gallstone ileus Mecomium (cystic fibrosis)	Inflammatory Process Crohn disease Diverticulitis Stricture from ischemia Radiation enteritis or stricture Medication-induced (NSAIDs, KCl tablets)	Hernias Abdominal wall Internal Volvulus External mass effect
Parasites (ascaris, diphylobothrium) Enterolith Intussusception	Neoplasms Primary intestinal or colon (malignant or benign) Secondary (metastasis or carcinomatosis)	Abscess Annular pancreas Pancreatic pseudocyst Carcinomatosis Endometriosis Pregnancy
Polypoid and exophytic lesions	Trauma (e.g., intramural hematoma)	

Pathophysiology of Intestinal Obstruction

Local Effects of Bowel Obstruction

When a loop of bowel becomes obstructed, intestinal gas and fluid accumulate. Stasis of luminal content favors bacterial overgrowth, alters intestinal fluid transport properties and motility, and causes variations in intestinal perfusion and lymph flow. Luminal contents and volume, bacterial proliferation, and alterations in motility and perfusion work in concert to determine the rate at which symptoms and complications develop. Each of these factors merits discussion in some detail.

Intestinal Gas. Approximately 80% of the gas seen on plain abdominal radiographs is attributable to swallowed air.⁶ Approximately 70% of the gas in the obstructed gut is inert nitrogen.¹⁰ Oxygen accounts for 10% to 12%, CO₂ for 6% to 9%, hydrogen 1%, methane 1%, and hydrogen disulfide 1% to 10%. In the setting of acute pain and anxiety, patients with intestinal obstruction may swallow excessive amounts of air. Passage of such swallowed air distally is prevented by nasogastric suction.

Intestinal Flora. An important contribution to normal digestive function comes from its bacterial population.¹¹ In patients with normal gastric acid secretion, the chyme entering the duodenum is sterile. The small numbers of bacteria that are found in stomach and proximal intestine are aerobic, gram-positive species found in the oropharynx. Distally, in the ileum and colon, gram-negative aerobes are present and anaerobic organisms predominate. Total bacterial counts in normal feces reach 10¹¹ organisms per gram of fecal matter. Control of the bacterial populations depends on intact motor activity of the intestines and the interactions of all species present. This ecology can be disturbed by antibiotic therapy or by surgical reconstructions that result in stasis within intestinal segments. Intestinal bacteria serve several functions, including metabolism of fecal sterols, releasing the small-chain fatty acids that are an important food source for colonocytes; metabolism of fecal bile acids, fat-soluble vitamins (e.g., vitamin K) and vitamin B12; and breakdown of complex carbohydrates and organic matter, leading to formation of CO₂, H₂, and CH₄ gases.⁹ Considerable evidence suggests that the normal flora may contribute to baseline levels of intestinal secretion and, perhaps, normal intestinal motility. Under baseline conditions, the small intestines in germfree animals are frequently dilated, fluid filled, and without peristalsis.^{12,13}

Table 49-2 Symptoms and Signs of Bowel Obstruction

Symptom/Sign	Proximal Small Bowel (Open Loop)	Distal Small Bowel (Open Loop)	Small Bowel (Closed Loop)	Colon/Rectum
Pain	Intermittent, intense, colicky, often relieved by vomiting	Intermittent to constant	Progressive, intermittent to constant; rapidly worsens	Continuous
Vomiting	Large volumes, bilious and frequent	Low volume and frequency, progressively feculent with time	May be prominent (reflex)	Intermittent, not prominent; when present, feculent
Tenderness	Epigastric or periumbilical; quite mild, unless strangulation is present	Diffuse and progressive	Diffuse, progressive	Diffuse
Distension	Absent	Moderate to marked	Often absent	Marked
Obstipation	May not be present	Present	May not be present	Present

Adapted from Schuffler MD, Sinanan MN. Intestinal obstruction and pseudo-obstruction. In: Sleisenger MH, Fordtran JS, eds. *Gastrointestinal Disease*. 5th ed. Philadelphia, PA: WB Saunders, Co.; 1993;898–916.

Figure 49-2. Schematic illustration of a closed-loop obstruction. The small intestine twists around its mesentery, compromising inflow and outflow of luminal contents from the loop. Also, the vascular supply to the loop may be compromised due to the twisting of the mesentery. The risk of strangulation is high.

In recent years, the role of bacterial toxins in mediating the mucosal response to obstruction has received increasing attention. In germfree dogs, luminal accumulation of fluid is not observed and absorption continues.¹³ In addition, it is well recognized that bacterial endotoxins can stimulate secretion, possibly via release or potentiation of activity of neuroendocrine substances and prostaglandins.¹² Finally, since a substantial part of systemic microvascular and hemodynamic responses to endotoxemia appear to be attributable to heightened synthesis of nitric oxide,^{14,15} it seems likely that mucosal response to local inflammation and endotoxin release will also be altered by conditions

modifying the synthesis or activity of nitric oxide. The role of nitric oxide in mucosal fluid and electrolyte movements is currently under active investigation.^{16,17}

Intestinal Fluid. Classical experimental studies established that fluid accumulates intraluminally with open- or closed-loop small intestinal obstruction.^{9,11,18} Factors contributing to the accumulation of fluid include intraluminal distention and pressure, release of prosecretory and antiabsorptive hormones and paracrine substances, changes in mesenteric circulation, and elaboration and luminal release of bacterial toxins. Experimental studies and clinical investigation^{19,20} demonstrated that elevation of luminal pressures above 20 cm H₂O inhibits absorption and stimulates secretion of salt and water into the lumen proximal to an obstruction. In closed-loop obstructions, luminal pressures may exceed 50 cm H₂O and may account for a substantial proportion of luminal fluid accumulation.²¹ In simple, open-loop obstructions, distention of the lumen by gas rarely leads to luminal pressures higher than 8 to 12 cm H₂O.²² In open-loop obstructions, the contributions of high luminal pressures to hypersecretion may not be important.

The release of endocrine/paracrine substances remains relatively uncharacterized in states of mechanical bowel obstruction.^{23,24} Suggestions have been made that vasoactive intestinal polypeptide (VIP) may be released from the submucosal and myenteric plexuses within the gut wall, promoting epithelial secretion and inhibiting absorption.^{24,25} Use of prostaglandin synthesis inhibitors has also implicated excess release of prostaglandins.²³ Further work may be expected to focus on the role of luminal factors such as irritative bile acids, proinflammatory agents such as endotoxin and platelet-activating factor,^{26–28} and messengers such as nitric oxide^{29,30} in coordinating responses of mucosal secretory and absorptive functions during intestinal obstruction.

Intestinal Blood Flow. Microvascular responses to intestinal obstruction may also play an important role in determining the hydrostatic gradients for fluid transfer across the mucosa into the lumen. In response to heightened luminal pressure, total blood flow to the bowel wall may initially increase.³¹ The breakdown of epithelial barrier structures and enzymatic breakdown of stagnant intestinal contents leads to increased osmolarity of luminal contents. In addition to secretory stimulation and absorptive inhibition of the mucosa, the simultaneous changes in hydrostatic and osmotic pressures on the blood and lumen sides of the mucosa favor flow of extracellular fluid into the lumen. Perfusion is then compromised as luminal pressures increase, bacteria invade, and inflammation leads to edema within the bowel wall.¹¹

Intestinal Motility. Obstruction of the intestinal lumen does not simply block distal passage of luminal contents. The accumulation of fluid and gas in the obstructed lumen also elicit changes in myoelectrical function of the gut, proximal and distal to the obstructed segment. In response to this distention, the obstructed segment itself may dilate, a process known as *receptive relaxation*.³² Such changes ensure that, despite accumulation of air and fluid, intraluminal pressures do not amplify easily to the point of compromising blood flow to the intestinal mucosa. At sites proximal and distal to the obstruction, changes in myoelectrical activity are time dependent. Initially, there may be intense periods of activity and peristalsis. Subsequently, myoelectrical activity is diminished and the interdigestive migrating myoelectrical complex pattern, is replaced by ineffectual and seemingly disorganized clusters of contractions.^{33–35} Similar alterations have been observed in experimental models of large bowel obstruction. Subsequent patterns of myoelectrical quiescence may correspond to increasing accumulation of fluid and air proximally and the attempt to prevent luminal pressures from rising. It is likely that many factors contribute to the rate at which these changes in myoelectrical activity occur.³⁶ These factors would include neurohumoral milieu, bacterial products, and luminal constituents.

Complications and Systemic Effects of Bowel Obstruction

Closed-Loop Obstructions. The complications of closed-loop obstructions evolve rapidly. The reasons for this rapid evolution are best understood by considering the simplest and most common form of closed-loop obstruction, appendicitis. When a fecalith obstructs the blind-ended appendix, secretion of mucus and enhanced peristalsis represent the initial attempt to clear the blockage. Intense crampy abdominal pain focused at the umbilicus results. Nausea and vomiting are not uncommon as a result of luminal obstruction but as a reflexive response to hyperperistalsis and stretching of the mesentery. Over the next 8 to 18 hours, continued secretion of mucus to high intraluminal pressures, stasis, bacterial overgrowth, mucosal disruption, and elevation of luminal pressures convert intermittent cramps to constant and worsening pain. When luminal pressure exceeds mural venous pressure and then capillary

perfusion pressures, inflammatory cells are recruited from surrounding peritoneal structures. This sequence of events leads to intense inflammation, release of exudate in the area of the appendix and the first localization of pain from the umbilicus to the area of peritoneum lying nearest the inflamed appendix. Peritoneal findings (localized tenderness, involuntary guarding, rebound, or referred tenderness) and fevers appear. Subsequently, 20 to 24 hours into the illness, the blood supply of the appendix is compromised. Gangrene and perforation follow and, if not contained by surrounding structures, free perforation leads to a rigid abdomen. Toxins from necrotic tissue and bacterial overgrowth are released into the systemic circulation and shock ensues. Torsion of a loop of small intestine around an adhesive band or inside a hernia leads to a similar pattern of events. As discussed below, torsions of the large bowel are usually accompanied by massive distention of the loop by air and feces, but the compromise of intestinal wall perfusion and evolution into peritonitis, systemic toxicity, and shock are similar.

Open-Loop Obstructions. Complications in open-loop obstructions do not necessarily evolve as rapidly as in closed-loop obstructions. Not uncommonly, an open-loop obstruction located in the proximal jejunum can be decompressed by the patient's ability to vomit. Proximal obstruction is characterized by vomiting and loss of gastric, pancreatic, and biliary secretions, with resulting electrolyte disturbances. These disturbances include dehydration, metabolic alkalosis, hypochloremia, hypokalemia, and usually hyponatremia. In contrast, obstructions of the distal ileum may lead only to a slowly progressing distention of the small intestine, with accommodation by intestinal myoelectrical function and minor alterations in fluid and electrolyte balances. Open-loop obstructions located in the midgut are often complicated by events similar to those seen in closed-loop obstructions or combinations of events seen in high and low obstructions (Table 49-2). Patients with distal jejunal obstruction tend to present with a combination of complications resulting from loss of intestinal contents from vomiting, as well as distention and compromise of intestinal wall perfusion.

2 In simple or uncomplicated obstruction, the intestinal lumen is partially or completely occluded without compromise of intestinal blood flow. Simple obstructions may be complete, meaning that the lumen is totally occluded, or incomplete, meaning that the lumen is narrowed but permitting distal passage of some fluid and air. In strangulation obstruction, blood flow to the obstructed segment is compromised and tissue necrosis and gangrene are imminent.

Clinical Presentation and Differential Diagnosis

3 The four key symptoms associated with acute mechanical bowel obstruction include *abdominal pain, vomiting, distention, and obstipation*. When bowel obstruction is the most likely diagnosis, "abdominal pain out of proportion to physical findings" represents a surgical emergency. Colon obstruction is usually accompanied by varying levels of pain with massive abdominal distention and obstipation. As noted earlier, the signs and symptoms of acute but simple small intestinal obstructions are related to the level of the obstruction and the closed- or open-loop nature of the obstruction. Other abdominal conditions, such as appendicitis, diverticulitis, perforated peptic ulcer, cholecystitis, or choledocholithiasis can usually be distinguished from SBO, by clinical examination and basic laboratory data. It should be emphasized that bowel obstruction can complicate any of these abdominal conditions. The presence of another abdominal process does not exclude the complication of SBO.

Over the years, numerous attempts have been made to use groupings of clinical criteria to establish the diagnosis of complete and irreversible intestinal obstruction, as distinguished from partial intestinal obstruction that might improve without operative intervention or other abdominal pathology. In recent studies, computer-assisted analysis has been used to identify such criteria.³⁷ Key factors in the history and clinical examination³⁸ include previous abdominal surgery, quality of pain (colic/intermittent versus steady), abdominal distention, and hyperactivity of bowel sounds. Not surprisingly, the use of such computer-assisted algorithms confirms that the most important clues to the diagnosis of simple obstruction of the small intestine are obtained in a complete and careful history and physical examination. As discussed below, the role of plain abdominal radiographs and other imaging studies is to confirm the clinical diagnosis of simple obstruction. It should be emphasized that, in simple obstruction, laboratory studies do not play a direct role in diagnosis, but aid in understanding the extent of complications such as dehydration, strangulation, and sepsis.

Strangulation obstruction is accompanied by symptoms and signs suggesting peritonitis, large fluid shifts, or systemic toxicity. These symptoms and signs include abdominal tenderness or involuntary guarding localized to the area of the strangulated loop of bowel, decreasing urine output, fever, and

tachycardia. There have been attempts to use common clinical and laboratory test criteria to identify the likelihood that the obstruction is associated with strangulation. Stewardson et al.³⁹ observed that the risk of strangulation was low in patients with partial (i.e., incomplete) or complete SBO if fever, tachycardia, localized abdominal tenderness, or leukocytosis were not present. These authors suggested that, in a setting consistent with bowel obstruction, any one of these four cardinal signs indicated a small risk for strangulation. The presence of any two of these signs increased the risk of strangulation so high as to warrant immediate surgery. These authorities and others have stressed, however, that when complete obstruction is present, no satisfactory clinical criteria are available to reliably exclude the possibility of strangulation.^{39–43}

Different laboratory tests have been advocated for early detection of strangulated intestine. Metabolic (i.e., lactic) acidosis and increases in serum amylase, inorganic phosphate, hexosaminidase, intestinal fatty acid-binding protein, and serum D-lactate levels have all been associated with intestinal ischemia.^{44,45} Such laboratory abnormalities may be helpful in diagnosing established strangulation in a small group of patients where the diagnosis of necrotic bowel is not clear. However, a noninvasive and rapid test has not yet been developed that can provide information to suggest that tissue necrosis is imminent but not yet established.⁴³

Radiographs and Imaging

Plain Films

The role of plain abdominal radiographs and imaging studies is to confirm the diagnosis of bowel obstruction, locate the site of obstruction, and gain insight into the lesion responsible for the obstruction. On plain radiographs of the abdomen, the key findings of SBO reflect the accumulation of air and fluid proximal, and clearance of fluid and air distal to the point of obstruction. Dilated loops of small intestine are defined as those greater than 3 cm in diameter. Free air represents perforation of a viscus and mandates immediate operation. Such findings include dilated loops of small bowel on the flat plate (Fig. 49-3) and multiple air–fluid levels located at different levels on the upright film or lateral decubitus film (Fig. 49-4). Based on these criteria plain abdominal radiography is diagnostic in 67% to 80% of patients.^{46,47} Plain radiographs, however are only accurate in 46% to 85% of the time and can miss SBO in patients without air–fluid levels because of fluid-filled distended loops.⁴⁸ In complete obstruction of the small intestine, the colon loops and rectum do not contain air. If there is air in the colon, the obstruction may be complete, but early, or it may be incomplete.

In the colon, tight closed-loop obstructions (i.e., volvulus of the cecum, transverse colon, or sigmoid colon) are accompanied by distention of the obstructed segment (Fig. 49-5). The proximal colon is considered dilated when it reaches 8 to 10 cm; the sigmoid colon is considered dilated at 4 to 5 cm. In contrast, obstruction by carcinoma or diverticulitis presents with massive distention of the entire colon from the point of obstruction to the ileocecal valve. From this standpoint, any large bowel obstruction may represent a “closed loop” if the ileocecal valve is competent. Although plain film findings can be used to differentiate obstruction of the small bowel from that of the large bowel, they are not consistently accurate in localizing the specific site of obstruction.

Figure 49-3. Plain supine abdominal film of a patient with small-intestinal obstruction. Note the multiple dilated loops of small

intestine (*black arrow*) in the left upper quadrant, characterized by complete markings of the plicae. Also note the absence of air in colon and rectum.

Figure 49-4. Plain upright abdominal film of a patient with small-intestinal obstruction. Note the air–fluid levels in the stomach and multiple dilated loops of small intestine (*black arrows*), and absence of air in the colon or rectum.

Figure 49-5. Plain upright abdominal film of a patient with sigmoid volvulus. The dilated centrally located sigmoid loop is seen (*arrowheads*). The proximal colon is dilated and gas filled. T, transverse colon; D, descending colon.

Contrast Studies

The diagnosis of bowel obstruction can generally be made by considering the clinical history, physical examination, laboratory, and plain radiograph findings. Contrast studies (i.e., small bowel follow-through, enteroclysis, and contrast enema) may provide specific localization of the point of obstruction and the nature of the underlying lesion. When obstruction of the small intestine is not progressing or resolving, a small bowel follow-through may be performed to confirm the presence and location of the obstruction. Also, even under acute circumstances, diagnosis and management of colonic obstructions are generally enhanced by the use of a contrast enema. Under some circumstances, however, contrast studies are unnecessary and may be contraindicated. For example, in the classic setting of abdominal pain, nausea, vomiting, and a plain film indicating multiple air–fluid levels in the small intestine and colonic collapse, the diagnosis of acute obstruction can be made clinically. Failure to improve in a short period of time will mandate operation and contrast studies are unnecessary. When strangulation or perforations are strongly suspected, contrast studies are contraindicated.

4 The choice of contrast materials includes water-insoluble suspensions of barium and water-soluble agents such as Gastrografin® or Hypaque®. Barium studies provide the clearest images, in both small bowel studies where the contrast is given from above and colon/rectum studies in which the contrast is

given by enema. If barium leaks into the peritoneum, it elicits intense peritonitis. If there is any possibility of bowel perforation or gangrene, barium should not be used. Water-soluble agents such as sodium amidotrizoate/meglumine amidotrizoate oral solution (Gastrografin®) or diatrizoate sodium/diatrizoate meglumine (Hypaque®) are hyperosmotic and can elicit fluid translocation into the gut. When the obstruction of the small intestine is incomplete the use of these agents may facilitate resolution. Gastrografin is hyperosmolar (1,900 mOsm/L). Its administration permits mobilization of fluid into the bowel lumen which decreases edema of the intestinal wall and increases the pressure gradient across obstructive site. It is thought that these fluid and pressure shifts can contribute to resolution in cases of incomplete obstruction. The 2013 Bologna guidelines for diagnosis and management of adhesive SBO recommended a dosage of 50 to 150 mL of Gastrografin administered either orally or via NGT immediately on admission or after an attempt of conservative treatment for 48 hours.⁴⁹ The appearance of contrast in the colon within 4 to 24 hours after administration had a sensitivity of 96% and specificity of 98% in predicting resolution of SBO.⁵⁰ A prospective randomized trial confirmed that gastrografin significantly reduced the need for surgery by 74%.⁵¹ Some studies showed that water-soluble contrast medium reduces hospital stay but does not reduce need for surgery^{52,53} but recent meta-analysis showed that it is effective in reducing the need for surgery and shortening length of stay.⁵⁰ Use of water-soluble contrast may thus be both diagnostic and can be therapeutic.

Computed Tomography and Other Imaging Modalities

5 The potential benefits of *computed tomography* (CT) scanning in diagnosis of bowel obstruction include the following.^{54–57} First, using radiographic contrast, the obstructing segment may be localized and characterized as complete or incomplete. Second, the nature of the obstructing lesion, especially if it is malignant, can be established. Third, additional abdominal pathology (e.g., metastases, ascites, parenchymal liver abnormalities) may be identified. Fourth, anatomic information obtained from the CT can be used in operative planning. There is also evidence that, in special circumstances, CT may improve preoperative detection of strangulation.^{42,56} Coronal and sagittal reconstruction improve the ability to identify transition point and IV contrast with delayed imaging should be considered to assess for venous occlusion or delayed bowel wall enhancement.⁵⁸ CT findings indicating the site of obstruction and impending ischemia include beak-like narrowing, mesenteric edema, vascular engorgement, moderate to severe intestinal wall thickening (greater than 2 mm) (Fig. 49-6). In addition, high attenuation of bowel wall on unenhanced CT scans, low or reduced attenuation of bowel wall on intravenous contrast CT scans, and presence of intramural air (pneumatosis) or portal venous gas are CT findings suggestive of strangulation. Attenuation reflects increased energy absorption, scattering, beam divergence, and other causes of energy loss. Thus, areas of high attenuation appear darker than areas of low attenuation. CT scan has a 96% sensitivity and 93% specificity with a negative predictive value of 99% in diagnosing intestinal strangulation.⁵⁹ Although CT scan need not be routinely performed unless history, physical examination, and plain films are not conclusive for SBO diagnosis,⁶⁰ it is increasingly the “go-to” study for confirmation.

Figure 49-6. Axial (A) and coronal (B) images of a closed-loop obstruction with strangulated small bowel secondary to a volvulus from an adhesive band. Distended fluid-filled loops of small bowel (B) in a radial distribution converge toward the point of torsion (*white arrows*). There is edema within the mesentery (M). Shown in (C) is a coronal view of vascular engorgement and mesenteric edema in a closed-loop obstruction.

Ultrasound has a very limited use in diagnosing SBO and visualization can be obscured by the intraluminal air but it has been suggested that real-time abdominal sonography could aid in the diagnosis of strangulation obstruction. In studies conducted in two different institutions, Ogata and colleagues^{61,62} demonstrated that the presence of significant amounts of peritoneal fluid and of an akinetic and dilated loop of bowel were strongly associated with the presence of strangulation. In patients who had strangulation, but were thought to have simple obstruction only, these findings helped to make the preoperative diagnosis of infarction.

Magnetic resonance imaging (MRI) has the sensitivity comparable to CT scan in diagnosing obstruction but limitations include lack of availability after hours, poor definition of mass lesion, and poor visualization of colonic obstructions.⁶³ The use of MRI should be limited to patients who have contraindications to CT or are allergic to contrast material.⁴⁹

It should be emphasized that when the clinical picture suggests strangulation, unnecessary imaging studies should not delay resuscitation or expeditious movement to the operating room. Such studies will not necessarily be helpful when clinical criteria and basic abdominal radiographs have indicated the presence of a simple and complete obstruction. By itself, this diagnosis mandates urgent exploration and the information sought should be weighed against the risk of delay in going to the operating room. In fact, in most studies evaluating the impact of imaging on diagnosis and timing of intervention, clinical diagnosis is seldom incorrect – it is highly specific when multiple clinical signs (tenderness, peritoneal signs, leukocytosis, and profound dehydration) of strangulation are present. However, such a picture represents advanced disease and use of CT scan may detect strangulation before such signs are manifest. These findings reinforce the dictum that when there are clinical signs of strangulation, surgery should be performed without delaying for additional imaging studies. In patients with equivocal findings or uncertain clinical diagnosis, CT can be highly useful in confirming the diagnosis, localizing the site and detecting the cause of intestinal obstruction and strangulation.⁵⁶

General Considerations in Management of the Patient with Bowel Obstruction

Patients with obstruction of the large bowel present with abdominal pain, distention, and obstipation. Vomiting and electrolyte imbalances are sometimes prominent, though usually delayed. Elderly patients, in particular, are prone to dehydration. The presentation of SBO depends on level of obstruction, open- or closed-loop nature, and interval since onset of symptoms. Symptoms and signs of pain, vomiting, obstipation, and distention are present in variable degrees. The overall picture, however, is usually one of a patient with abdominal symptoms that are evolving and getting worse. In the settings described previously, the following questions must be addressed as expeditiously as possible:

1. *Is the abdominal pain disproportionate to the physical findings and laboratory studies?*
2. *How rapidly the symptoms and signs are evolving: minutes, hours, or less acutely?*
3. *Does the patient suffer from dehydration, electrolyte imbalance and acid–base disturbance?*
4. *Is the obstruction complete or incomplete?*
5. *Is there a possibility of strangulation?*

Clinical data and basic laboratory studies will provide reliable information to answer the first three questions. Answering questions 4 and 5 will often depend on close clinical observation and reexamination in the first hours or days after presentation. Abdominal radiographs and imaging studies are frequently used to provide additional information to help answer these latter questions, as well as providing information to identify the obstructing lesion.

Summarized in [Table 49-3](#) are thumbnail sketches of different, but typical, kinds of patients presenting with symptoms and signs consistent with obstruction of the small intestine. The principles of diagnosis and management of each of these patients begins with clinical information that indicates the likelihood of a bowel obstruction. Laboratory studies and plain abdominal films are used to confirm the diagnosis of obstruction and determine the extent of physiologic impairment. The patient's history and clinical course in the first few hours of observation are used to determine the likelihood of strangulation. Indications for surgery include rapid evolution of symptoms and signs and the diagnosis that the obstruction is complete. Contrast or imaging studies are used only when symptoms are not evolving rapidly and when identification of the underlying lesion might alter the operative strategy (see specific lesions later).

Table 49-3 Diagnosis and Decisions in Bowel Obstruction in Three Hypothetical Patients

	Patient I Closed-Loop Obstruction	Patient II Intestinal Obstruction With Strangulation	Patient III Open-Loop Obstruction of the Distal Small Intestine or Cecum
Clinical	Crampy periumbilical pain worsening over last 12 hrs. Two to three episodes of emesis. No distension, minimal flatus	Diffuse, crampy abdominal pain over 2 days with many episodes of vomiting. No bowel movements or flatus. T 100°F, P 100, dehydrated. Mild distension; local tenderness lower abdomen	Progressive abdominal distension over previous 2 wks. Mild discomfort. No vomiting. Few bowel movements and little flatus. Distension prominent, mild tenderness, no peritoneal findings
Lab	No leukocytosis, pH or electrolyte disturbances	WBC 16K. Serum Na ⁺ low, K ⁺ low, Cl ⁻ low, pH alkalotic	WBC normal, serum electrolytes mildly decreased
X-ray	Nonspecific gas pattern on plain film	Multiple dilated loops and air–fluid levels. No gas in colon	Multiple dilated small bowel loops and air–fluid levels. Some gas and stool in proximal colon
Differential Dx	Broad: includes appendicitis, closed-loop SBO, pancreatitis, nonsurgical conditions	Narrow: complete SBO likely, strangulation cannot be excluded	Narrow: distal small bowel or proximal colon obstruction likely, possibly incomplete
Initial Rx	Admit with q3–4h reevaluation by clinical examination, WBC. Repeat films q8–12h. NG tube if vomiting persists. IVFs	Admit for rapid resuscitation with IVFs, IV antibiotics. Urinary catheter and NG intubation indicated	Admit for IVFs, NG intubation. Hypaque enema followed by barium to evaluate colon. CT if malignancy suspected
Indications for surgery	If pain worsens, local tenderness or peritoneal signs evolve, WBC rises, and urine output falls	Already present. Patient should be scheduled and brought to OR after adequate resuscitation (dramatic improvement with resuscitation may permit observation for 4 hrs)	Surgery performed when evaluation is complete or if clinical course deteriorates during evaluation

6 The initial management of all patients with suspected bowel obstruction includes designating the patient “NPO” and starting intravenous fluids comprised of isotonic Ringers or normal saline solutions. Restoration of fluid and electrolyte balance is a priority, often requiring frequent evaluation of serum electrolytes and pH. In rapidly evolving cases or patients with significant dehydration, an indwelling

urinary catheter should be placed to monitor urine output. Invasive hemodynamic monitoring (e.g., a Swan–Ganz catheter) may be necessary to monitor the response to fluid resuscitation in patients with severe cardiac, pulmonary, or renal insufficiency.

Nasogastric decompression is indicated in most cases. The nasogastric tube, typically a 16- or 18-Fr sump tube, serves to prevent distal passage of swallowed air and minimizes the discomfort of refluxing intestinal content. The use of longer tubes has been advocated in certain settings, especially for patients with chronic but intermittent obstruction arising from Crohn disease, peritoneal carcinomatosis, radiation enteritis, or many previous laparotomies for obstruction. The underlying rationale is that advancement of the tip of the long tube to the obstructed loop would permit more effective decompression, perhaps resulting in relaxation of the loop and relief of the obstruction. A number of studies have failed to document benefits in the use of long tubes^{64,65} in helping to resolve partial intestinal obstruction or prolonged ileus. Recently, a more possibly effective version of the long tube has been described, the ileus tube (Create Medic, Tokyo), which is made of silicon is 300 cm in length, is 16 Fr wide and has three channels. This tube is advanced with endoscopic guidance and has been reported in one study to be more effective (89.6 vs. 46.7%) compared to NGT group, specifically with respect to the intervals to resolution of symptoms and radiographic findings.⁶⁶ Caution should be undertaken on the potential risk of development of pneumonia and respiratory failure in routine use of NGT.⁶⁷

A randomized controlled trial suggested that resolution of partial SBO could be accelerated with the use of a regimen of oral adjunctive therapy that included magnesium oxide (500 mg), simethicone (40 mg) and *Lactobacillus acidophilus* (0.3 g tablet) given three times daily via NGT was effective in hastening the resolution of the conservatively treated partial adhesive SBO and shortening the hospital stay with no difference in complication rate and recurrence. Magnesium oxide was used due to its laxative side effects. Simethicone, a defoaming agent, was used because it alters surface tension of gas bubbles and causes them to coalesce, thereby accelerating the passage of gas through the intestinal tract. *Lactobacillus*, a probiotic, may have multiple benefits, including improved digestion and prevention of overgrowth of pathogenic bacterial species.^{67a}

Recent study showed the potential beneficial effects of hyperbaric oxygen (HBO) therapy at a pressure of 2.0 atmospheres absolute with 100% oxygen given once a day up to 7 days. HBO therapy was associated with earlier resumption of oral intake (4.7 days vs. 5.6 days; $p = 0.001$), shorter hospital stay (10.3 days vs. 14.1; $p = 0.001$) and lower operative rate (7.4% vs. 14.8%).⁶⁸ It is postulated that intestinal edema is decreased through the osmotic effect of oxygen. Oxygenation under high pressure enhances inert gas diffusion from the closed intestinal lumen into the blood. Relaxation of the distended intestinal loop improves the compromised microcirculation and oxygenation of hypoxic intestinal tissue which leads to preservation of intestinal viability and recovery of motility. This modality may be an option in the management of patients with high anesthesiologic risk.⁶⁹ A current study (HOT Trial) is underway to find out the clinical value of HBO therapy in obstruction due to radiation-induced fibrosis (ISRCTN 86894066).

The use of intravenous antibiotics in the initial management of bowel obstruction should be discussed as well. Clinically, it has been recognized that antibiotics can ameliorate the evolution of symptoms and signs of strangulation in closed-loop obstruction and appendicitis. Studies in humans have demonstrated that, even in simple obstruction, bacterial counts in succus rise from under 10^6 organisms/L to over 10^9 organisms/L⁷⁰ and are not necessarily reduced with short-term administration of antibiotics.⁷¹ Moreover, experimental studies indicate that bacteria can translocate across the intestinal mucosa, passing into lymph channels.⁷² Further studies have demonstrated that germfree animals can survive strangulation obstruction longer than normal animals and that luminal fluid taken from obstructed segments in germ-free animals is much less toxic than fluid taken from normal animals.^{73,74}

For all these reasons, it is a well-established practice to administer antibiotics perioperatively, in order to reduce wound infection and abdominal sepsis rates in patients undergoing operation to relieve intestinal obstruction, simple or strangulated. Once the decision has been made to proceed with surgery, broad-spectrum antibiotics, covering gram-negative aerobes and anaerobes should be given. A second-generation cephalosporin or a combination of a first-generation cephalosporin and metronidazole is a rational practice for perioperative coverage in both simple and strangulation obstruction. Nevertheless, the use of antibiotics in patients who have not yet been committed to operation has not been evaluated systematically. Giving antibiotics to patients who are being observed can obscure the underlying process and, in the end, delay optimal therapy.

The decision to perform abdominal exploration to relieve intestinal obstruction should be made

expeditiously, but not in the absence of critical information or before adequate resuscitation (Algorithm 49-1). Indications for surgery are outlined in Table 49-3, for each of the thumbnail vignettes. It should be emphasized that once a diagnosis of complete obstruction is made, simple or strangulated, the operation should proceed without undue delay. It is reasonable to commit the patient to a period of observation when the diagnosis is uncertain (i.e., there is a possibility of a nonsurgical diagnosis or that the obstruction is not complete). A practical point is that obstruction occurring in a patient without a previous history of laparotomy is not likely to be caused by peritoneal adhesions. This is known as *de novo* obstruction and whatever the underlying cause will not usually resolve without operation.

Specific Types of Bowel Obstruction

Chronic Adhesions

As noted previously, peritoneal adhesions account for more than half of SBO cases. Lower abdominal procedures such as appendectomy, hysterectomy, colectomy, and abdominoperineal resection are common precursor operations to adhesive obstruction. Adhesions form after any abdominal procedure, however, including cholecystectomy, gastrectomy, and abdominal vascular procedures. In long-term follow-up, about 5% of patients undergoing laparotomy will develop adhesive obstruction; of these, 10% to 30% will suffer from additional episodes.^{75,76} Up to 80% episodes of SBO due to adhesions may resolve nonoperatively.^{39,40,53,64} However, an index episode and three recurrences indicate a likelihood of over 80% that there will be more recurrences.⁷⁵ Surgical management of an acute episode appears to reduce subsequent recurrence rates from ~15% to ~6%,⁷⁶ but no studies have been able to establish whether the immediate benefit of laparotomy for any given episode of simple adhesive obstruction outweighs the overall benefit of expectant management and operation only for serial recurrences. Thus, a previous history of a laparotomy simply provides a reasonable basis for expectant management of patients in whom it is not yet possible to diagnose a complete obstruction. Ultimately, patients who present with signs and symptoms of bowel obstruction are managed according to the CT findings and clinical course.

Algorithm 49-1. Algorithm for the management of adhesive small bowel obstruction.

The pathobiology of adhesion formation has been the subject of considerable investigation.¹¹ Histologic examination of chronic adhesions reveals foreign body reaction, usually to talc, starch, lint, intestinal content, or suture. Talc and starch are found less commonly now than previously, because of

improvements in techniques of manufacture and sterilization of surgical gloves. Mesothelial cells are the presumed origin of tissue plasminogen activator (TPA). TPA binds fibrin and plasminogen, thereby preventing adhesion formation. In early studies, inflammatory cells, including mast cells,⁷⁷ were implicated in the process that produces adhesions. Recent studies^{78,79} have emphasized the role of various cytokines in exacerbating or inhibiting adhesion formation in different animal models. Biologically active substances that might prove useful in preventing postoperative adhesions include transforming growth factor beta (TGF-beta) and vascular endothelial growth factor (VEGF), both of which may be targeted for inhibition without less fear of compromising the response to bacterial infection.^{78,79}

Current strategies to prevent adhesions after a first laparotomy include targeting the fibrinolytic system, which enhances rapid healing and appears to minimize formation of peritoneal adhesions.⁷⁸ Attempts to minimize or prevent adhesion formation have resulted in development of hyaluronic acid-carboxymethylcellulose membrane (Seprafilm, Genzyme, Cambridge, MA). This compound mechanically prevents adhesion formation by physically separating adjoining tissues. It is absorbed by the body in 7 days and thus is present only during the phase of fibrosis, and not as a persistent foreign body. Randomized trials have suggested that this compound prevents, minimizes severity, and decreases density and vascularity of adhesions.^{78,80} Other trials and review of 17 RCT corroborate decreased incidence, extent, severity, density, and vascularity of adhesions but not total prevention of adhesions or reduction of the incidence of subsequent bowel obstruction,⁸¹ and caution not be placed on anastomosis due to increased rate of anastomotic leak.⁸² Seprafilm and similar barriers have been advocated for use in patients in whom a second abdominal procedure is planned or significant adhesions anticipated (e.g., Hartmann procedure, ileal pouch anal anastomosis with protecting ileostomy, pelvic surgery, gynecologic procedures, staged hepatic surgery and colon surgery) – though it has been proposed for all surgeries by the manufacturers. The largest randomized, single blind, controlled study on Seprafilm showed that the incidence of adhesive small bowel requiring reoperation was significantly lower for Seprafilm patient with absolute reduction rate of 1.6% and relative reduction rate of 47%.⁸³

The Prevention of Postoperative Adhesion (POPA) study uses 2,000 icodextrin 4% solution before abdominal closure and follow-up upto 10 years showed that it is safe and reduces intra-abdominal adhesion formation and the risk of reobstruction (2.19% vs. 11.1%).⁸⁴ Small trials showed the potential use of hydrogen adhesion barrier spray⁸⁵ and lyophilized human peritoneal membrane.⁸⁶

More important than pharmacologic approaches, however, are the efforts of the surgeon to pay meticulous attention to hemostasis and surgical technique, the avoidance of excessive tissue dissection, and careful search and removal of any extraneous material. The use of laparoscopic approaches, when feasible, should lower the likelihood of pathological adhesions as well.⁸⁷

Early Postoperative Adhesions

Obstruction in the immediate period following abdominal surgery is uncommon but may occur in up to 1% of patients in the 4 weeks following laparotomy. Adhesions are responsible for approximately 90% of such cases and hernias for approximately 7%.⁸⁸ Intussusception, internal herniation, inflammation, abscess, intramural intestinal hematoma or technical errors may be responsible for the remainder of cases.^{89–91} Most cases occur after surgery of the colon, especially abdominoperineal resections, or operations in the lower abdomen. It is rare for upper abdominal surgery to cause such obstructions. A common scenario is that a patient will undergo colectomy uneventfully, pass flatus and have bowel sounds by postoperative day 3. On the fourth postoperative day the patient suddenly becomes distended and uncomfortable, and stops passing flatus and stool. Patients with acutely evolving symptoms and signs represent complete obstruction and should be managed as such. In this latter setting, the mortality may be as high as 15% due to delays in recognition and operative intervention. The loss of bowel sounds after a short period of normal or hyperactive activity is worrisome for ischemia of the obstructed segment. The vast majority of such cases may be treated as partial intestinal obstruction; nasogastric suction and intravenous fluids will help resolve symptoms within a few days ([Algorithm 49-2](#)). When the clinical course does not demand earlier intervention, a nonoperative approach may be tried for 10 to 14 days and will resolve the obstruction in over 75% of such cases.^{88,90,92} It is recently noted that patients who experienced early postoperative adhesions may have a higher risk of developing adhesive SBO (26.5% vs. 7.5% at 5 years; $p < 0.001$).⁹¹

Bowel Obstruction after a Bariatric Procedure

The obesity epidemic sees the growth in the number of bariatric procedures which includes gastric banding, sleeve gastrectomy, gastric plication, roux-en-y gastric bypass, and biliopancreatic diversion

with or without duodenal switch. Band slippage can occur in 15% to 20% of patients and typically presents with a history of upper abdominal symptoms of reflux, regurgitation, and dysphagia. Upper GI study is the preferred method of diagnosing band slippage showing the evidence of malposition of the band and proximal pouch dilatation with obstruction. The initial management is urgent band deflation using Huber needle and if this is unsuccessful or patient is acutely unwell, necrosis, abscess, or erosion must be considered which may require surgery. Intestinal obstruction occurs in 4.4% after roux-en-y gastric bypass. The etiology of obstruction includes internal hernia (53%), roux limb compression due to scarring (20%), adhesion (14%), stricture at gastrojejunal anastomosis, kinking of the alimentary limb, incisional hernia, and intestinal intussusception. The most common site of internal herniation is mesojejunal mesenteric window, followed by Petersen window and the mesocolic window.⁹³ It is paramount to differentiate bariatric from nonbariatric patients presenting with SBO since there are significant differences in their management. Nonoperative management was successful in 72% of non-postbariatric patients but surgery was performed in about 62% of postbariatric surgery patients with SBO. Also, the bariatric group is most likely to undergo laparoscopy (5% vs. 2%), abdominal wall reconstruction (38% vs. 9%) and is less likely to require colostomy (1% vs. 13%). The bariatric group underwent surgery sooner within an average of 24 hours compared to 3.3 days in non-postbariatric patients.⁹⁴

Algorithm 49-2. Approach to the management of malignant bowel obstruction.

Figure 49-7. Computed tomography images of an inguinal hernia. Axial (A) and coronal (B) CT scan images showing incarcerated right inguinal hernia with air- and fluid-filled loop of small bowel (arrowhead) in the right inguinal canal (arrow) causing small bowel obstruction with dilated loops of proximal small bowel (B).

Hernia

Hernias of all types are second only to adhesions as the most frequent causes of obstruction in Western countries. External hernias such as inguinal (Fig. 49-7) or femoral hernias may present with the symptoms of obstruction and will not be diagnosed unless sought.⁹⁵ Femoral hernias are particularly prone to incarceration and bowel necrosis due to the small size of the hernia inlet.⁹⁵ Other hernias such as umbilical, incisional, paracolostomy, or lumbar hernias are obvious. Still others, such as internal hernias are usually diagnosed at laparotomy for obstruction. These include obturator hernias, paraduodenal hernias (Fig. 49-8), and hernias through the foramen of Winslow or mesenteries. When hernia has been identified as the cause of the obstruction, the patient is quickly resuscitated, given antibiotics, and taken to the operating room. The hernia is then reduced and the viability of the bowel assessed. If viable, the bowel is left alone; if not, it is resected. The hernia defect is then repaired. One important consideration is the Richter hernia (Fig. 49-9).⁹⁶ In this variant, only a portion of the wall of the bowel is incarcerated and thus incarceration and strangulation may not be associated with complete obstruction. These most frequently occur in association with femoral or inguinal hernias. Complete obstruction can occur if more than half of the bowel circumference is incarcerated.

For external (abdominal wall) hernias, it may be possible to perform *taxis*, that is, the manual reduction of an incarcerated/irreducible hernia. Reduction (*taxis*) of the hernia is usually successful. Occasionally *taxis* results in reduction of the contents of the hernia sac *en mass* (still obstructed), reduction of strangulated bowel resulting in generalized peritonitis, or reduction of an obstructed Richter hernia.⁹⁷⁻¹⁰¹ This is one reason for using circumsection in relying on *taxis* as a mode of treatment for incarcerated inguinal, femoral, and incisional hernias. In general, *taxis* should be followed expeditiously by operative repair.

Gallstone Ileus

As a result of intense inflammation surrounding a gallstone, a fistula may develop between the biliary tree and the small or large intestine. Most fistulae develop between the gallbladder fundus and duodenum. If the stone is greater than 2.5 cm in diameter, it can lodge in the narrowest portion of the terminal ileum, which is just proximal to the ileocecal valve. This complication is rare, accounting for less than 6 in 1,000 cases of cholelithiasis and no more than 3% of cases of intestinal obstruction. Typically, the patient is elderly female and presents with intermittent symptoms over several days, as the stone tumbles distally toward the ileum. The classic findings on plain radiographs include those of intestinal obstruction, a stone lying outside the right upper quadrant, and air in the biliary tree (Fig. 49-10). Treatment includes removal of the stone and resection of the obstructed segment only if there is evidence of tissue necrosis. The risk of a recurrent gallstone ileus is about 5% to 10%.^{102,103} Such recurrences usually occur within 30 days of the initial episode and are usually due to stones in the small

intestine that were missed at the original operation.

The difficult decisions in management of gallstone ileus focus on the fistula. The arguments in favor of disconnecting the fistula and removing the gallbladder have been the possibility of recurrence of gallstone ileus and the risk of cholangitis due to reflux of intestinal content into the biliary tree. When the latter operation is included, the mortality may be doubled as compared to simple removal of the gallstone. It is used selectively in good-risk patients. The long-term incidence of biliary tract infections has not been common enough to warrant the more aggressive approach at the initial operation. Some authors have advocated cholecystectomy at a second operation, especially if the patient is young and fit. The consensus is that cholecystectomy should not be performed at the initial operation for gallstone ileus, except in highly selected patients. A careful search of the entire intestine should be performed to exclude the possibility of additional large stones which can occur in up to 25% of patients.¹⁰²⁻¹⁰⁴

Figure 49-8. Paraduodenal hernia. **A:** Plain film of closed-loop obstruction with neck of the closed loop in the right upper abdomen. **B:** Computed tomography scan showing slippage of the jejunum behind the stomach, with dilatation and obstruction of the duodenum. **C:** Schematic diagram showing relationships of the paraduodenal fossa and transverse mesocolon.

groin. **B:** Schematic diagram showing Richter hernia, in which the antimesenteric border (but not the whole wall) of the intestine is incarcerated.

Figure 49-10. **A:** Plain radiograph of a patient with gallstone ileus, showing obstructed loops of small intestine (*black arrow*) in the abdomen and a gallstone (*white arrow*) in the pelvis (gallstone was initially misinterpreted as an EKG lead [*black arrow*]). **B:** Computed tomography (CT) scan showing a cholecystoduodenal fistula (*black arrow*) with air in the biliary tree (D, duodenum). **C:** CT scan showing gallstone (*white arrow*) in the distal ileum and fecalization of luminal content adjacent to the stone.

Intussusception

About 5% of intussusceptions occur in adults. An intussusception occurs when one segment of bowel telescopes into an adjacent segment, resulting in obstruction and ischemic injury to the intussuscepting segment ([Fig. 49-11](#)) and the obstruction may become complete, particularly if tissue inflammation and necrosis occur. Of adult cases, 90% are associated with pathologic processes.^{105,106} Tumors, benign or malignant, act as the lead point of intussusception in more than 65% of adult cases. A significant proportion of cases have been reported to occur after abdominal surgery for lesions other than neoplasm. In cases not associated with neoplasm, Sarr et al.¹⁰⁶ reported that approximately 20% were related to the suture line, approximately 30% to adhesions, and approximately 60% to intestinal tubes. Intussusception related to long tubes can occur when the tube is withdrawn, but most frequently occurs with the tube in place. Perioperative intussusception frequently subsides without intervention.

Four types of intussusception are recognized: enteric ([Fig. 49-12](#)), ileocolic, ileocecal, and colonic. In the ileocolic form, the ileum telescopes into the colon past a fixed ileocecal valve. In the ileocecal form, the valve itself may be the lead point of the intussusception. Radiographic features of intussusception are not specific. Plain films reveal evidence of partial or complete obstruction. Occasionally, a sausage-shaped soft tissue density will be seen, outlined by two strips of air. Recently, in both pediatric and adult cases, it has been suggested that sonography may be useful in diagnosis. Nevertheless, the mainstays of diagnosis are contrast studies or CT scan. Because of the high incidence of tumors, surgery has generally been recommended. Reduction by hydrostatic pressure, which is the standard of care in pediatric cases, is not usually attempted in adults. Honjo et al. described preoperative reduction in 31.8% and 31.8% intraoperative reduction of adult intussusceptions. Preoperative reduction serves several functions including avoidance of emergency surgery, allowing radical surgery for cancer, reducing the extent of intestinal resection, and allows time for preoperative predation of the bowel. This may shift the paradigm in management of adult intussusception.¹⁰⁷ Clear indications for operation include long length and wide diameter of the intussusception, presence of a lead point, or evidence of bowel obstruction.¹⁰⁵ Recent studies have called into question the need to operate in all cases detected on sensitive imaging studies such as CT scan, arguing that a number of these patients can be safely managed without operation.¹⁰⁵ However, in the opinion of these authors, it is difficult to advise

expectant management except in unusual circumstances.

Figure 49-11. Anatomy of intussusception. The intussusceptum is the segment of bowel that invaginates into the intussusciens.

Figure 49-12. Axial (A) and coronal CT scan (B) images of an ileocolic intussusception secondary to colon carcinoma (M) as a lead point. Intussusceptum (*long arrows*) and intussusciens (*arrowhead*). Mesenteric vessels and fat (*white arrowhead*) accompany the intussusceptum.

Crohn Disease

Indications for surgery in Crohn disease are discussed elsewhere in this book. In this disease, obstruction occurs under two different sets of circumstances.¹⁰⁸ When the disease has flared acutely, the lumen may be narrowed by a reversible inflammatory process. The result is an open-loop obstruction that may respond, first to intravenous hydration and nasogastric decompression, and ultimately to therapy with corticosteroids or other anti-inflammatory regimens. Alternatively, obstruction may occur in the setting of a chronic stricture. Such strictures will not respond to conservative measures and, once diagnosed, operative therapy should not be delayed. One important clinical point is that about 7% of strictures in the colon, and an uncertain proportion of those in the small intestine, are malignant.¹⁰⁸ Extent of resection is thus based on intraoperative findings, that is, to margins beyond visibly diseased bowel and does not necessarily include enlarged lymph nodes in the mesentery. If there is suspicion for malignancy, a lymphadenectomy is performed.

A second clinical point is that Crohn-affected bowel may not be dilated proximal to the obstruction but can be complicated by a small perforation. Such a microperforation may not be large enough to be associated with free air on plain films. The patient may thus present with significant abdominal pain and tenderness. A CT scan is likely to be the most sensitive imaging modality for obtaining evidence that differentiates conditions that require immediate surgery (closed-loop obstruction and microperforation) from simple obstruction that would otherwise be observed. In the absence of clinical progression of symptoms and signs, however, extended conservative management is warranted before the patient is committed to surgery.

Malignant Obstruction

Obstruction can complicate malignancies of the small and large bowel in a number of settings. Studies have documented that 10% to 28% of patients with colorectal cancer and 20% to 50% of patients with ovarian cancer will present with a malignant bowel obstruction at some point during the course of their disease.¹⁰⁹ Most commonly, a primary lesion such as an adenocarcinoma or lymphoma will enlarge until the lumen of the intestine is blocked. The lesion then presents with symptoms and signs associated with the level of obstruction and are managed accordingly.

A second setting involves a patient who previously has undergone surgery for malignancy and now returns with evidence of bowel obstruction. The likelihood that the obstruction is due to recurrent disease is based on several factors, including the origin of the primary malignancy, the stage of the primary malignancy, and the designation of the original surgery as curative or palliative. Gastric and pancreatic carcinomas often present with or are subsequently complicated by peritoneal carcinomatosis and thus the subsequent obstruction is most likely due to malignancy. With respect to colon and rectal carcinomas, as many as 50% of cases presenting with obstruction after resection of the primary may be due to adhesions and not recurrent malignancy.^{109,110} In addition, even if the obstruction is now due to unresectable disease, significant palliation can be obtained through bypass or enterostomy in up to 75% of patients (Fig. 49-13). However, the underlying diagnosis of cancer in this patient population mandates careful attention be paid to patient selection prior to any surgical intervention and risk factors for poor outcome (Table 49-4, Algorithm 49-2). In patients presenting with gastroduodenal and colorectal obstructing lesions who are not candidates for surgical bypass or enterostomy, endoscopic management options including percutaneous endoscopic gastrostomy (PEG) tube placement and self-expanding metallic stent (SEMS) placement, are available (Algorithm 49-2). These options have been associated with symptomatic relief in greater than 75% of patients.¹⁰⁹

Figure 49-13. Significant palliation can be achieved in a patient with obstructing but unresectable malignancy. Enteroenterostomy is performed to bypass the obstructing segment.

Management of incurable malignant obstruction may require an approach that moves away from classical surgical teaching of nil by mouth, nasogastric tube, intravenous fluids, and serial radiographs.¹¹¹ Patients with advanced malignant obstruction in the absence of a solitary or correctable obstructing lesion are generally managed without surgery (Algorithm 49-2). Patients are managed without a nasogastric tube if possible. They are encouraged to eat as soon as obstructive symptoms resolve using a low-fiber diet. Antiemetics and opioids via continuous subcutaneous infusions are used to manage nausea, vomiting, and colic, respectively. In addition, octreotide, a somatostatin analog, is used in palliation of refractory malignant intestinal obstruction by improving intestinal mucosal absorption, improving motility, reducing gastrointestinal hormone levels and intestinal secretions, and having a direct antineoplastic effect on the obstructing tumor.¹¹² This allows true palliative care outside a hospital setting saving patients the pain, discomfort, and complications of hospitalization and

unproductive surgery.¹¹¹

Volvulus

The term *volvulus* indicates that a loop of bowel is twisted more than 180 degrees about the axis of its mesentery. Volvulus has been reported for the cecum, transverse colon, splenic flexure, and sigmoid colon. A special variant of volvulus, complicating a condition known as *Chilaiditi syndrome*, can occur when redundant loops of the transverse colon slip between the liver and diaphragm and then undergo torsion.¹¹³ Generally, the condition is asymptomatic, but when associated with volvulus must be relieved surgically.

Table 49-4 Results of Management of Malignant Obstructions: Risk Factors for Unfavorable Outcome

Advanced age (biologic/physiologic)
Poor performance status
Advanced stage of primary malignancy (previous treatments, availability of anticancer options, life expectancy)
Malnutrition/cachexia
Comorbidities
Absence of psychosocial support
Ascites (>100 cc associated with poor outcome)
Single vs. multiple sites of obstruction
Carcinomatosis (believed to respond poorly to surgical intervention)

The most common site for volvulus is the sigmoid colon, accounting for 65% of cases.¹¹⁴ By definition, a volvulus is a form of closed-loop obstruction of the colon. Air is always present in the colon and rectum, and thus volvulus of any segment of the colon is associated with abdominal distention and, usually, severe abdominal pain. As shown in [Figure 49-5](#), the most common radiographic feature is the “bent inner tube” appearance of the sigmoid, which is located in the upper abdomen. The preferred method of management involves endoscopic decompression. A rigid or flexible proctosigmoidoscope is advanced gently into the rectum until a rush of air and feces indicates that the loop has been untorsed. A rectal tube is then advanced well into the loop as a stent to prevent retorsion. Gangrene of the colon does not usually complicate the picture if the patient is seen and treated promptly. This conservative approach resolves the volvulus in 85% to 90% cases and elective resection or fixation of the redundant segment can then be planned. Following endoscopic decompression, recurrence of the volvulus is higher than 60%.¹¹⁵ Thus, an operation to remove the sigmoid should be performed if the patient is fit for surgery.¹¹⁶ However, a majority of these patients are elderly and infirm and approximately 15% have a history of psychiatric disorder. As a result, the patient may present with peritoneal findings, sepsis, and shock. In this setting, rapid resuscitation followed by urgent resection and colostomy is warranted. Other forms of volvulus generally cannot be detorsed without operation. Fixation of the torsed segment (e.g., via cecostomy or cecopexy) is generally a less satisfactory solution than resection of the involved segment and is not generally recommended.¹¹⁴

Radiation Enteritis

After asymptomatic periods lasting at least 10 years, chronic intestinal obstruction can result. Radiation injury elicits an underlying vasculitis and fibrosis that lead to chronic, recurring low-grade partial obstruction of the small intestine or stricturing and bleeding in the colon and rectum. Operation is indicated for incapacitating symptoms and obstruction not resolved by conservative management.¹¹⁷ Recurrence of the original tumor as a cause of obstruction should be considered and excluded. However, the diffuse nature of the injury and pathologic responses can lead to massive resections that leave the patient with short-bowel syndrome. Attempts to suture scarred loops can also result in chronic inflammation and formation of interloop abscesses and fistulae. The incidence of suture line leak is high.¹¹⁸ There are several experimental therapies used in the treatment and prevention of radiation enteritis which includes pentoxifylline–tocopherol combination, sulfasalazine, methylprednisolone, HBO, intraperitoneal octreotide, cysteine, triamcinolone, and amifostine.^{119,120}

Role of Laparoscopy in Management of Small Bowel Obstruction

Open surgery is the preferred method in the management of strangulating SBO after failed conservative management but since the advent of laparoscopy for general abdominal surgery, a number of investigators have reported the feasibility of laparoscopic approaches to small and large bowel obstruction. Such approaches have been used, with varying degrees of success, to manage obstruction from a number of different etiologies (Table 49-5).¹²¹⁻¹²³ Laparoscopic management of bowel obstruction provides many potential benefits including quicker recovery of bowel function, shorter hospital stay, less postoperative pain, reduced recovery time and early return to full activity, and fewer postoperative complications including a decreased incidence of wound infection and pneumonia. Additionally, as suggested by both clinical and experimental studies in animal models, laparoscopy is associated with decrease in incidence, extent and severity of intra-abdominal adhesions compared with open surgery.^{124,125} Thus laparoscopic management of bowel obstruction may result in a decreased lifetime risk for recurrent bowel obstruction. According to a systematic review and meta-analysis, laparoscopic adhesiolysis was associated with reduced overall complication rate with no significant difference in the occurrence of intraoperative injury to bowel and overall mortality.¹²⁶

Table 49-5 Results for Outcome of Laparoscopic Management of Intestinal Obstruction: Favorable Attributes

Diaphragmatic (hiatal) hernia	Gallstone ileus
Inguinal hernia	Intussusception
Incisional hernia	Adenocarcinoma of colon
Femoral hernia	Diverticulitis
Spigelian hernia	Colitis (ischemic, radiation)
Internal hernia	Volvulus
Adhesions	Benign colon tumors
Chron disease	Periappendicular abscess
Small bowel tumor	Carcinomatosis
Meckel diverticula	Ogilvie syndrome
Ingested foreign body	Bezoar

Table prepared by William Peranteau, MD.

In adults, the most common etiology for which laparoscopic versus open surgical management of bowel obstruction has been evaluated is adhesive bowel obstruction.^{123,127-136} Studies of laparoscopic lysis of adhesions for SBO indicate that it is feasible, with acceptable operative times, length of hospital stay, as well as conversion and complication rates (Table 49-6). Studies directly comparing laparoscopic to open surgical management of adhesive SBO highlight the benefits of the laparoscopic approach as indicated by statistically significant decreases in complication rates, time to return of bowel function, length of hospital stay, and even overall cost (Table 49-7).

Despite these benefits, laparoscopic management of bowel obstruction should be approached with caution and individualized to specific clinical situations.¹³⁷ Laparoscopy is discouraged when the surgeon is uncomfortable with the technique or in patients presenting with peritonitis, hemodynamic instability, severe comorbid conditions, complete and distal obstruction, or when contraindications to pneumoperitoneum exist. Recent advancement and improvement in tools and skill in laparoscopy have paved the way for its increased use in the surgical management of SBO. Recently, consensus guidelines have been published emphasizing its role in selected group of patients.¹³⁸ Laparoscopically assisted lysis of adhesions may be attempted in case of first episode of SBO or anticipated single-band lesion. While it may be problematic to use a laparoscopic approach in managing obstruction in patients who have previously undergone extensive and open intra-abdominal procedures, it is safe to use a laparoscopic approach in managing obstruction in patients who have previously undergone laparoscopic procedures, especially focused procedures such as appendectomy and cholecystectomy.

Under these circumstances, success in using laparoscopy to confirm the diagnosis of obstruction is between 60% and 100%; its success in therapeutic resolution of the obstruction is lower, perhaps 40% to 80%. The predictive factors for a successful laparoscopic adhesiolysis are less than 2 previous laparotomies, nonmedian previous laparotomy, appendectomy as previous surgical treatment, unique band adhesion as pathogenetic mechanism of SBO, early laparoscopic management within 4 hours from onset of symptoms, no signs of peritonitis on physical examination, and experience of surgeon.¹³⁹ There should be a low threshold for open conversion. The usual reasons for converting to open adhesiolysis are inadequate laparoscopic control due to intestinal distention, extensive adhesions, iatrogenic perforations, bleeding, and resection of necrotic segments.¹⁴⁰ Operative technique plays a paramount

role in the success of laparoscopic approach. In obtaining laparoscopic access, an open access (Hasson) technique, entry to the left upper quadrant and ultrasound-guided site entry were recommended.^{49,138} Although recent studies suggest that laparoscopic approaches are safe, effective and beneficial, prospective randomized studies evaluating laparoscopic management of SBO are required to definitively document its benefits over the traditional open approaches. It is also important to point out the need for adhesion quantification in future research. Coccolini et al. proposed a peritoneal adhesion index ranging from 0 to 30, providing a more precise and standardized system for describing findings at operation.¹⁴¹ Such standardization would enable integration of the results of different studies, permitting a better understanding of circumstances where treatments may be standardized and those where individualization is important.

Table 49-6 Outcomes and Complications of Laparoscopic Operations for Obstruction of the Small Intestine Due to Adhesions

Reference	Operative Time (min)	Conversion (%) ^a	Bowel Injury (%)	LOS (Days)	Reoperation (%)	Success (%)	Mortality (%)
Pekmezci et al.	99	6.7	6.7	4	0	100	0
Levard et al.	NR	40.9	8.4	4	4.5	95	2.2

^cLaparoscopic postoperative complications: pulmonary (1.9%), wound infection (5.8%), anastomotic leak (3.8%).
^dOpen intraoperative complications: perforation (13.5%), mesenteric injury (1.9%).
^eOpen postoperative complications: pulmonary (3.8%), cardiac (3.8%), DVT (1.9%), death (3.8%), wound infection (11.5%).
Table prepared by William Peranteau, MD.

7 Open exploratory laparotomy is the gold standard in treating unresolved SBO, but laparoscopic management should be considered in select group of patients. Types of intestinal obstruction that are more likely to lead to strangulation and the need for urgent/emergent operation include closed-loop obstructions, obstruction that occurs without a prior history of operation, and obstructions that occur after laparoscopic procedures.

ILEUS AND PSEUDO-OBSTRUCTION

Ileus

Etiologic Factors

8 An *ileus* or “eileos” (Greek for “twisting”) reflects a loss of forward peristalsis and coordination of the motility of the different regions of the gastrointestinal tract causing a functional obstruction.¹⁴² Clinically, bowel sounds, passage of flatus, and bowel movements have been used to signal the return of bowel function and coordination of peristalsis. Liquid contrast and radiolabeled marker studies suggest that effective duration of ileus varies in different regions of the alimentary tract.^{143,144} A POI may last for 0 to 24 hours in the small intestine, 24 to 48 hours in the stomach, and 48 to 72 hours in the large bowel.^{145,146} The type of surgery and the wide variety of endpoints used to measure gut recovery often decide the duration of ileus. There is no consensus as to which one is most clinically meaningful. Duration of ileus is therefore primarily dependent on the return of colonic motility and its coordination with other regions of the gastrointestinal tract. A typical period of ileus is thus self-limited and easily tolerated. Factors implicated in ileus (Table 49-6) are outlined below:

Neurohumoral Peptides. Increases in endogenous neuromuscular inhibitors of the bowel include norepinephrine, corticotropin-releasing hormone (CRH), nitric oxide, somastostatin, glucagon, gastric inhibitory peptide, opioids and other peptides such as calcitonin gene-related peptide, motilin, substance P, VIP, and substance P, have all been established as inhibitory neurotransmitters in the intrinsic gut nervous system. Antagonists to VIP, substance P and inhibitors of NO synthesis improve postoperative bowel motility.^{147,148} Calcitonin gene-related peptide inhibits postoperative gastric emptying and gastrointestinal transit.^{149,150} The use of anticholinergic medications delays recovery of an ileus.¹⁵¹

One group of neurohumoral substances that are particularly important in this regard are the opioids, both synthetic and endogenous. Opioids are established neurotransmitters in central and peripheral nervous systems, and it is well established that their use delays gastric emptying and promotes nonpropulsive smooth muscle contraction with an increase in intraluminal pressure throughout the entire gastrointestinal tract.^{152,153} Over the years, a series of experimental studies have indicated that recovery of ileus is accelerated during administration of specific antagonists to kappa or mu opioid receptors,^{154,155} suggesting that endogenous opioid release modulates recovery from ileus.

Inflammation. A relatively recent series of experimental and clinical investigations have focused attention on the role of inflammatory cells and mediators of inflammation in the development of prolonged ileus. Surgical intervention results in elevated levels of interleukin-6 (IL-6), cyclooxygenase isoform COX-2, and inducible nitric oxide synthetase (iNOS), all mediators of inflammation from macrophages.^{156,157} In experimental animals, focal manipulation of the bowel may result in a pan-enteric inflammation and ileus.¹⁵⁷ In experimental animals and human subjects, activated macrophages have been found in the muscularis of the small bowel, as early as 3 hours after laparotomy.¹⁵⁸ Increased COX-2 expression leads to prostaglandin release. Jejunal contractility appears to be impaired, an effect blocked in COX-2 knockout mice and by the administration of selective COX-2 inhibitors. In related studies both in experimental animals and human subjects, Kalff et al. found that NO synthesis is stimulated in activated macrophages in the muscular layer of the small intestine following surgical intervention. More recently, degranulation of mast cells has also been implicated in the pathogenesis of ileus after laparotomy. In this regard, it has been shown that surgical manipulation of intestines activates quiescent macrophages as well as mast cells, and that mast cell destabilizers can prevent mechanically induced intestinal inflammation and dysmotility.^{159,160} Bowel wall edema from inflammation or intravenous fluid overload is another mechanism of impairment of GI motility.¹⁶¹

Table 49-8 Etiologies of Prolonged Ileus After Abdominal Operations

Neurogenic	Metabolic	Pharmacologic	Infectious
Spinal cord lesions or injury	Hypokalemia Uremia	Anticholinergics Opiates	Systemic sepsis Pneumonia
Retroperitoneal process hematoma, tumor	Ca ⁺⁺ , Mg ⁺⁺ imbalance	Autonomic blockers	Peritonitis
Ureteral colic	Hypothyroidism Diabetic coma or ketoacidosis	Antihistamines Psychotropics Phenothiazines Haloperidol Tricyclic antidepressants Clonidine Vincristine	Herpes zoster Tetanus Bacterial overgrowth (blind-loop)

Inhibitory Neural Reflexes. Noxious spinal afferent signals are thought to increase inhibitory sympathetic activity in the gastrointestinal tract.¹⁶² Blockade of spinal afferents with epidural local anesthetics or with topical capsaicin has been shown to accelerate resolution of ileus in experimental studies.^{149,150} In clinical studies of patients undergoing complex abdominal operations through conventional laparotomy incisions, it appears that conventional intramuscular injections are less likely to be associated with prolonged ileus than strategies utilizing patient-controlled intravenous injection.^{163,164} Moreover, utilization of epidural analgesia tends to decrease recovery times from ileus in this group of patients,^{165–167} suggesting that autonomic pathways coursing through spinal cord may serve as control points for ileus. Recent studies also provide evidence that carbon monoxide, derived from the activity of heme oxygenase-2 in myenteric plexus of the intestine, may play a role in modulating smooth muscle activity and its regulation by enteric nervous system.^{168–170}

Central responses have also been observed as a result of laparotomy¹⁶² and have been linked to activation of afferent pathways in the vagus nerve and a general response of the organism to stress and release of corticotrophin-releasing factor.¹⁷¹ Very recently, the efferent pathways in the vagus have also been implicated as possible modulators or control points for the inflammatory response. A series of experimental studies^{172,173} has suggested that the vagus participates in suppression of certain macrophage activities, leading to earlier resolution of intestinal ileus.¹⁷³ These observations offer the possibility of a multidimensional understanding of ileus, both in individuals who are recuperating normally and in those who have protracted ileus but no specific risk factors for it (e.g., undrained sepsis, overuse of narcotics, spinal cord injury, severe pelvic fractures, and retroperitoneal inflammation).

Diagnosis

It is important to distinguish between a normal *POI* and a *paralytic ileus*. The distinction is predominantly one of time since operation and based on circumstance. *POI* is less severe, self-limiting (lasts 2 to 3 days vs. 3 to 5 days) and is usually an indicator of colonic dysmotility rather than a paralytic ileus which represents inhibition of small bowel activity. A prolonged *POI* (*PPOI*) occurs with protracted signs or symptoms of abdominal distention, bloating, diffuse and persistent abdominal pain, nausea, vomiting, and inability to pass flatus or tolerate an oral diet.

It is also important to distinguish between a *PPOI* from a mechanical *SBO*. Clinically, the presence of intense colicky pain, feculent emesis, or rapidly progressing pain or distension is more suggestive of *SBO* than *PPOI*. Localized tenderness, fever, tachycardia, and peritoneal signs suggest bowel ischemia or perforation, necessitating emergent surgical intervention.¹⁰

A variety of clinical circumstances and laboratory tests may also increase suspicion for prolonged ileus and lessen concern for mechanical obstruction and associated complications. In addition to opiates, a number of medications have been associated with slow recovery of intestinal motor function (Table 49-8). Isolated metabolic disturbances such as ketoacidosis, hypomagnesemia, hypercalcemia, and hypokalemia can prolong ileus. Ileus can be caused and perpetuated by systemic inflammatory responses to sepsis, abscess, pneumonia, and pancreatitis.

9 When the patient's *POI* has extended beyond the expected period, plain films of the abdomen reveals gas in segments of both small and large bowel (Fig. 49-14). At this point, the patient may begin to experience some discomfort and distention, as swallowed air fills loops that do not have effective peristalsis. Bowel sounds may be present, if hypoactive. The differential diagnosis now includes the possibility of mechanical obstruction from early postoperative adhesions (see earlier). To differentiate early postoperative obstruction from ileus, contrast studies or CT scans are helpful. The latter may be useful if other abdominal pathology such as an abscess could be contributing to the clinical picture. *CT with oral contrast has a sensitivity and specificity of 90% to 100% in distinguishing ileus from a complete postoperative SBO.*¹⁷⁴ However, it is less reliable in distinguishing ileus from a partial *SBO*.¹⁷⁴ If the diagnosis is uncertain after CT, upper GI contrast studies (enteroclysis) with water-soluble radio-opaque contrast material (e.g., Gastrografin) are especially helpful in distinguishing ileus from partial *SBO* (which more closely mimics ileus than complete *SBO*) and in identifying the severity of partial obstruction.¹⁷⁴

Figure 49-14. Plain supine abdominal radiograph of a patient with ileus. Air–fluid levels are present in the small intestine (*thin arrow*). Gas is seen in the colon (*thick arrowhead*). These findings are characteristic of, but not specific for, ileus. Surgical drains in the pelvis and skin staples (*short arrow*).

Management

10 A normal POI is usually self-limiting. Nevertheless, there are a number of interventions that are effective in reducing the duration of a normal postlaparotomy ileus ([Table 49-9](#)). Midthoracic epidurals with neuraxial local anesthetics has been shown to hasten the return of bowel function compared to systemic or epidural opioids.^{165–167} Midthoracic local anesthetic epidurals block nociceptive afferent signals from the surgical site as well as sympathetic efferent outflow; this is useful for 48 to 72 hours postoperatively.

The goals in management in the normal period of postoperative ileus are to prevent uncomfortable distension, vomiting, and aspiration. Classic studies^{6,10} indicate that flatus and the air accumulating during intestinal distension is derived largely from swallowing. Under normal circumstances, flatus is passed as early as 30 minutes after a “test bolus” of air is administered by tube into the stomach. Thus, passage of flatus is used, in reliable patients, as the index indicating coordination of all segments of the gastrointestinal tract and resolution of ileus.

For many years, the mainstay of therapy was the use of nasogastric suction to prevent accumulation of swallowed air and secreted fluids in an alimentary tract not yet coordinating flow distally. Subsequent studies have demonstrated that the putative benefit does not compensate for risks of aspiration and discomfort of the tube. Thus, in routine abdominal cases such as colectomy, nasogastric tubes are used selectively^{175,176} in patients who are felt to be at risk of complications of ileus, based on the surgeon’s judgments about intraoperative findings or manipulations – prolonged handling and packing of the bowel, anticipation of intensive use of narcotics or other antikinetic agents, presence of sepsis or peritonitis, or extensive blood loss. Otherwise, a nasogastric tube is used for a short postoperative period or never placed, with the expectation that a small percentage of patients will require placement for symptoms.¹⁷⁶ In these patients, the patient is allowed nothing more than sips or ice chips until there is evidence (by listening for bowel sounds or the patient’s report of “rumbles”) that ileus is likely resolving. Intravenous fluids are necessary until the patient can be advanced to full intake of their requirements, usually after flatus is passed.

Table 49-9 Treatment for Postoperative Ileus

Treatment	Benefit	Drawback
Nasogastric tube	Possible relief of vomiting and bloating	Does not shorten duration of ileus May contribute to fever, atelectasis, and aspiration Discomfort
Early postoperative feeding	Stimulates reflex for propulsive bowel motility and enzyme secretion Stimulates immune system Reduces postoperative and posttraumatic infectious complications Reduces risk of anastomotic dehiscence, wound infection, pneumonia	Patients may not tolerate feeding
Opioid antagonists (Alvimopan)	Peripheral acting FDA approved to hasten postoperative ileus following partial large or small bowel resection with primary anastomosis	Possible cardiovascular or neoplastic risk Currently restricted to in-patient use only
Laparoscopic procedures	Earlier return of bowel function and discharge from hospital Minimal skin incision, minimal mechanical bowel manipulation	Not all patients and procedures are amenable to laparoscopic approach
Epidural anesthetics/analgesics	Reduced duration of ileus vs. systemic opioid Increases splanchnic blood flow Anti-inflammatory	Risks associated with epidural catheter placement
Gum chewing	May shorten duration of ileus Simple and inexpensive	Limited data
Laxatives	May shorten duration of ileus Inexpensive	Limited data on efficacy
Nonsteroidal anti-inflammatory drugs (COX-2 inhibitors)	Decreases opioid needed for pain control May increase motility by acting as an anti-inflammatory	Possible increased risk of postoperative bleeding Other adverse effects

Adapted from Luckey A, Livingston E, Tache Y. Mechanisms and treatment of postoperative ileus. *Arch Surg*. 2003;138(2):206–214, Table 2.
Prepared by Zain Khalpey, MD.

In addition correctable conditions such as electrolyte disturbances or uremia are investigated and rectified. Mobilization has other benefits in reducing morbidity.^{177,178} Early feeding is thought to stimulate gastrointestinal hormones, secretions and motility, and coordinated propulsive activity. In addition early feeding may improve immune function, reduce¹⁷⁹ infectious and catabolic complications.^{142,180} Despite the use of laxatives with prokinetic agents, no controlled trial exists to assess the possible beneficial effects of laxatives on POI.¹⁴²

One treatment, gum chewing, has attracted attention as a simple and inexpensive method of accelerating return of bowel function. Mastication stimulates the cephalic vagal cholinergic pathways that increases gastrointestinal hormone secretion such as gastrin, pancreatic polypeptide, and neurotensin which affects gastrointestinal motility.^{181,182} Since the initial publication of one small and underpowered study,¹⁸³ a number of prospective randomized trials have been conducted to test the hypothesis that gum chewing results in earlier passage of flatus and bowel movement in patients undergoing laparoscopic colectomy.^{184,185} No conclusive evidence has been obtained to demonstrate a clear benefit of gum chewing, although subgroup analysis suggests some patients may benefit.¹⁸⁵ At the same time, prospective randomized studies continue to be performed, arguing one conclusion or the other.^{186–190} According to one hypothesis sorbitol and other hexitols, the key gradients of “sugar-free” chewing gums may also play a role in the earlier recovery of POI.¹⁹¹ A recent study¹⁹² argued that nicotine gum might accelerate resolution of postoperative ileus through enhancement of vagal activation.

Salt and water disturbances in the body also may influence return of bowel function following laparotomy. In one study, patients undergoing colectomy received a restricted perioperative fluid resuscitation regimen or a standard, more liberal fluid resuscitation. The “restricted” group had a quicker passage of flatus and moved their bowels earlier, leading in part to shorter hospital stays.¹⁹³ Subsequent studies^{194,195} have not uniformly suggested that recovery from ileus is faster with temperance in fluid resuscitation; or have indicated that there is a benefit from fluid restriction protocols but have not reported return of gastrointestinal function as an endpoint.¹⁹⁶ However, this benefit, as well as others, may be more clearly observed when fluid therapy is directed by physiologic assessments of volume status, such as esophageal Doppler monitoring of the great vessels and heart chambers.^{197,198} A double-blind, randomized controlled clinical trial showed that Doppler-guided intraoperative fluid management decreases postoperative nausea, vomiting, ileus and wound infection.¹⁹⁹

Experimental evidence of pharmacologic interventions specifically directed at abnormal surges of

neurotransmitters or hormones that might prolong ileus have provided a useful insight into the pathophysiology of POI. Opioid antagonists, somatostatin analogs, sympatholytics, injection of local anesthetics into mesenteric nerve roots, or nonsteroidal anti-inflammatory agents, such as ketorolac, appear to promote faster recovery to normal myoelectric activity and intestinal transit times.^{151,200,201} The peripherally acting, selective μ -opioid receptor antagonist alvimopan (Entereg™) has been reported to reduce GI recovery time and to facilitate hospital discharge for both open and laparoscopic colorectal surgery cases,²⁰² after gynecologic surgery,²⁰³ after bowel resection, and after radical cystectomy.²⁰⁴ Importantly, in one study, the effect of alvimopan accelerated recovery after open abdominal surgery as an independent influence in an accelerated recovery program²⁰⁵ from colectomy.

Prokinetic agents such as metoclopramide, cisapride (presently not approved by U.S. Food and Drug Administration), and erythromycin have been evaluated for their efficacy in shortening the duration of POI. For ileus following upper gastrointestinal procedures (e.g., pancreaticoduodenectomy), such medications may be effective in promoting gastric emptying.^{206–211} For general abdominal procedures involving the small intestine, colon, and retroperitoneal structures such as the aorta, there has been limited success in using such agents to shorten recovery times.¹⁷⁹ In multiple controlled studies, metoclopramide did not have significant impact on the duration of ileus.^{212–214} In other studies, no benefit was observed when patients were given erythromycin. Promising results have been observed with cisapride and related agents,^{179,206,208} which significantly reduced the duration of ileus. The results would depend on the route of its administration. However, this medication is no longer approved for use in the United States due to the occurrence of potentially fatal arrhythmias.²¹⁵ In a Cochrane review of fifteen systemically acting prokinetic drugs, the conclusion was that erythromycin has no effect and there are insufficient evidence to recommend cholecystokinin-like drugs, cisapride, dopamine antagonist, propranolol, or vasopressin. IV lidocaine and neostigmine might show a potential effect but more evidence is needed.¹⁷⁹ Mosapride, a selective 5-hydroxytryptamine 4 receptor agonist has been shown to reduce the duration of POI in animal and human studies.²¹⁶ Escin, a natural mixture of triterpene saponins extracted from dried seeds of horse chestnut (*Aesculus hippocastanum* or *chinensis*) also may shorten time to recovery of gastrointestinal motility.²¹⁷

Along with pharmacologic measures, it should be emphasized that, in otherwise routine laparotomy or laparoscopy, gentle handling of tissues, meticulous attention to hemostasis, and applications of sound principles of wound management are likely to have the greatest impact on optimizing recovery from ileus and minimizing the incidence of prolonged ileus. Efforts to reduce incision size and time spent handling the intestines through the use of laparoscopic approaches clearly improves recovery from ileus in some if not all patients undergoing standardized intra-abdominal procedures such as appendectomy,²¹⁸ and colectomy.²¹⁹ Even in open procedures,²²⁰ standardization of management and effective communication help expedite clinical fast-track pathways and facilitate earlier recovery of bowel function and discharge from hospital.^{142,198,221} Currently proposed measures to minimize the prolongation of ileus are summarized in Table 49-10.

Table 49-10 Measures to Prevent Prolongation of Ileus

Minimization of trauma to tissues; using proper technique in the operating room with gentle handling of bowel during surgery
Minimal use of narcotics for analgesia, for any route of administration (intravenous, intramuscular, epidural)
Use of opioid antagonists (Alvimopan)
Generous use of midthoracic epidural anesthesia with local anesthetic use
Use of nonsteroidal anti-inflammatory (COX-2 inhibitors) agents for analgesia
Early feeding
Correction of any electrolyte or metabolic imbalances
Early recognition of septic complications (e.g., abdominal abscess, pneumonia, and central line sepsis) that may contribute to prolongation beyond the expected period for ileus

Colonic Pseudo-Obstruction (Ogilvie Syndrome)

Etiologic Factors

Acute pseudo-obstruction of the colon, also known as *Ogilvie syndrome*,²²² is a paralytic ileus of the large bowel, characterized by rapidly progressive abdominal distention, often painless.²²³ Although the

distention of the colon is not due to mechanical obstruction, the wall of the bowel, particularly that of the cecum, can become sufficiently distended so that its blood supply is compromised. Gangrene, perforation, peritonitis, and shock can follow. In 95% of the cases there are underlying diseases.^{223,224} Less than 5% of the cases occur in the absence of other conditions.

Major risk factors for development of Ogilvie syndrome include traumatic injury (11%), infections such as pneumonia, sepsis (10%); obstetric/gynecologic conditions (10%); myocardial infarction and congestive heart failure (10%); abdominal and pelvic surgery (9%); neurologic conditions such as Parkinson disease, spinal cord injury, multiple sclerosis, and Alzheimer disease (9%); orthopedic procedures (7%); other medical conditions including metabolic imbalances, for example, hypokalemia, hypocalcemia, hypomagnesemia (32%); and other surgical conditions (12%).^{222,224} Evidence suggests that Ogilvie syndrome is thought to be related, at least in part to sympathetic nervous overactivity or interference with sacral parasympathetic efferents, although there is little direct experimental evidence for this.²²³ It is postulated that the distal colon becomes atonic on interruption of the S2 to S4 parasympathetic nerve fibers. Other theories about the pathophysiologic causes include autonomic dysfunction, reduced colonic ganglion cells, and loss of intrinsic nitric oxide activity but the cause remains unknown.²²⁵

Diagnosis

This syndrome is commonly encountered in patients hospitalized over 3 to 7 days, often in men more than 60 years of age. Primary manifestations variably include gastrointestinal symptoms such as nausea, vomiting, abdominal pain, constipation, and diarrhea.^{223,224} Labored breathing, caused by abdominal distention, may be observed as part of the clinical picture. Other than distension, there are no characteristic physical or laboratory findings for this syndrome. On percussion the abdomen is resonant due to the presence of air in dilated segments of small intestine and colon. Sounds from the small intestine are present and may not be high pitched, as they are in intestinal obstruction.

Laboratory findings associated with this syndrome may include hypokalemia, hypocalcemia, hypomagnesemia, and hypophosphatemia, which are implicated as etiologic factors. Leukocytosis, elevation of sedimentation rate or c-reactive protein is also present if low-grade systemic inflammation is present or perforation is impending.

The diagnosis is usually apparent from plain film radiographs of the abdomen which may reveal air in the small bowel and distention of discrete segments of the colon (i.e., cecum or transverse colon often up to splenic flexure) or the entire abdominal colon. Haustral markings disappear with increasing distension. In doubtful cases and when bowel necrosis is not a significant worry, a hypaque contrast enema can establish the nonmechanical nature of the dilatation. Alternatively, colonoscopy can be diagnostic as well as therapeutic. Features suggesting the complication of bowel ischemia may include localized tenderness, worsening leukocytosis, metabolic acidosis, evidence of sepsis, or a rapidly deteriorating clinical course.

It is important to differentiate this syndrome from toxic megacolon and mechanical obstruction before establishing a final diagnosis. Mechanical obstruction of the colon, occurring in volvulus or obturator obstructions from cancer or diverticular disease, presents with acute pain along with distension. In contrast, pseudo-obstruction is less often associated with acute pain and more likely to present with discomfort due to distention. However, lack of pain in postoperative patients on opiates or elderly patients cannot exclude mechanical obstruction. In plain x-rays, the pathognomonic signs of mechanical obstruction such as lack of gas in the distal colon or rectum, and air–fluid levels in small intestine on x-ray can also be seen in Ogilvie syndrome. CT scan is currently the standard method for identifying colon pseudo-obstruction and excluding other forms of obstruction.²²³ Patients with toxic megacolon may manifest typically with symptoms such as fever, tachycardia, abdominal tenderness, bloody diarrhea or other manifestations of chronic inflammatory bowel disease along with “thumb printing” on the appearance of the abdomen on plain x-ray film in upright posture. Flexible sigmoidoscopy is contraindicated if toxic megacolon is thought to be likely, but it or contrast enemas²²³ can be useful diagnostically and therapeutically if toxic megacolon is thought unlikely.

Management

Initial management includes resuscitation and correction of any underlying metabolic or electrolyte imbalances (Table 49-11). Patients should have physical examination and plain abdominal radiographs serially to correlate colonic diameters in order to determine which case needs colonoscopic decompression or surgery. If the patient is not very uncomfortable and the colonic distension is no greater than 12 cm, conservative treatment can be continued for 1 to 2 days. It may be helpful to place

the patient in a prone position or at the knee chest position with hips held high, alternating right and left lateral decubitus position each hour. A nasogastric tube is helpful if the patient is vomiting and will prevent swallowed air from passing distally. When bowel ischemia is suspected, surgery is indicated. If bowel necrosis is found, the affected segment is resected and an ileostomy or colostomy should be performed. If the bowel is viable, a cecostomy is placed to vent the colon and prevent distention.

If, initially, the distention is painless and the patient shows no signs of toxicity or bowel ischemia, expectant management is successful in about 50% of cases.^{223,226} The risk of spontaneous perforation is approximately 3%, with attendant mortality of 50%. In most patients acute colonic pseudo-obstruction usually resolves within 3 days.^{223,227} If worsening and cecal diameter increases beyond 10 to 12 cm or if it persists for more than 48 hours, intervention is recommended. The duration of distention may be more important than the absolute size of the cecum with respect to spontaneous perforation. Colonoscopy should only be performed by experienced endoscopists. Endoscopic decompression is successful in 60% to 90% of cases, but the condition can recur in up to 40%. This rate of recurrence may be decreased by placement of a decompressive tube. Recurrence would require repeated colonoscopic decompression in approximately 40% of cases after initial successful decompression. The placement of a decompression with the aid of a guidewire at the time of colonoscopy may reduce the need for repeated colonoscopic decompression. Rectal tubes are ineffective as primary modalities in managing distention of the proximal colon. Such tubes may be useful in promoting passage of air and feces after colonoscopy but should not be used as a substitute for colonoscopic decompression. Percutaneous endoscopic left-sided colostomy (PEC), a minimally invasive technique, can be used to treat pseudo-obstruction provided these cases are carefully selected in the hands of a skilled endoscopist because of a high failure rate caused by infection.²²⁸

Table 49-11 Treatment for Pseudo-Obstruction

Treatment	Benefit
Nasogastric tube	Prevention of swallowed air from passing distally
Neostigmine	Increase motility through its parasympathomimetic action Premedication with colonoscopic decompression adding benefits
Erythromycin	Increases intestinal motility through motilin receptors in intestinal wall
Colonoscopic decompression	Prevention of complications such as perforation
Surgical interventions: total colectomy, Hartmann procedure, percutaneous endoscopic cecostomy	Required in case of refractory medical therapy

In anecdotal reports, prokinetic agents such as cisapride and erythromycin have been used to treat Ogilvie syndrome with some success. Erythromycin acts by binding to motilin receptors in the small intestine, causing intestinal smooth muscle contraction and perhaps better coordination with colonic motor function. Anecdotal reports have suggested the success of erythromycin treatment on either intravenous route for 3 days or oral route for 10 days.^{229,230} However, the relative paucity of motilin receptors in colon smooth muscle may explain why erythromycin is only anecdotally effective in relieving colonic pseudo-obstruction. Successful resolution of pseudo-obstruction has been reported with sympatholytic agents or spinal sympathetic block. The efficacies of these modalities have not been systematically evaluated.^{223,231}

Neostigmine, a parasympathomimetic, is used in the treatment of acute colonic pseudo-obstruction. The decompression with this drug has been achieved in 80% to 100% with a recurrence rate of 5%.²²³ Neostigmine may be a viable alternative to colonoscopy in pregnant women, provided mechanical obstruction is properly excluded. The administration of a polyerthylene glycol electrolyte balanced solution after initial resolution of colonic dilation may reduce the recurrence rate with use of neostigmine.²³²

Neostigmine has expected cardiovascular side effects such as bradycardia, hypotension, and dizziness; and is excreted via the kidneys. The few relative contraindications to its use in treatment of acute colonic pseudo-obstruction are a baseline heart rate of less than 60 beats per minute or systolic blood pressure of less than 90 mm Hg; active bronchospasm requiring medication; a history of colon cancer or

partial colonic resection; active gastrointestinal bleeding; pregnancy; or a serum creatinine concentration of more than 3 mg/dL (265 µmol/L). Other side effects would include mild to moderate crampy abdominal pain, excessive salivation and vomiting. Side effects such as increasing airway secretions and bronchospasm, can be reduced by concomitant use of glycopyrrolate without reduction of colonic response.^{233,234} Ponec et al.²³⁵ recommend use of neostigmine prior to colonoscopy, based on its easy administration, lower expense, and superior results in comparison to colonoscopy. Reported rates of response to treatment with neostigmine are 91% (single administration) and 100% (second administration) in a group of 21 randomized patients.^{223,235} Colonoscopy is associated with morbidity of 3% and mortality of 1%. Further studies of this combination therapy are warranted. It should be emphasized however, that patients should undergo immediate exploration if they exhibit signs of clinical deterioration or bowel perforation (peritoneal signs on physical examination or free air on radiographs).

Surgery is reserved for patients not responding to medical and endoscopic management and for patients who develop signs of peritonitis or perforation. Percutaneous endoscopic cecostomy can also be performed if case conservative measures fail.²³⁶ Cecostomy tubes are often poorly tolerated because of issues related to skin breakdown; in the authors opinion, this approach is advisable only when more extensive surgical procedures are considered too risky. Procedures such as total colectomy, ileostomy, and Hartmann procedure are taken into consideration in case of perforation.²²³

Chapter 50

Crohn Disease

Scott R. Steele and Eric K. Johnson

Key Points

- 1 Crohn's occurs anywhere along the gastrointestinal (GI) tract from mouth to anus and may present with one or more disease patterns – fistulizing, inflammatory, and fibrostenotic.
 - 2 The indications for operating on Crohn disease involve managing complications of the disease, not cure.
 - 3 Consider the patient's disease state and medical therapy for Crohn disease in the decision-making for surgery – this may require concomitant diversion in this patient population.
 - 4 Whenever possible, preserve length of the small intestine and avoid extensive resections when not required.
 - 5 Similar to ulcerative colitis, Crohn disease is associated with an increased long-term risk of developing colorectal cancer compared to the general population.
 - 6 Asymptomatic Crohn disease (e.g., perianal fistula) does not necessarily require treatment.
 - 7 Crohn disease is associated with a propensity for loose bowel movements and nonhealing wounds. Think of function first when treating perianal disease, and avoid overaggressive procedures on the sphincter that may alter continence.
-

INTRODUCTION

1 While many have heard the renowned account that Crohn disease derives its eponymous name more from the alphabetized listing of its authors (Crohn, Ginzburg, and Oppenheimer) in the 1932 *JAMA* publication “Regional ileitis: a pathological and clinical entity,”¹ some may not realize that it was a surgeon, Dr. A.A. Berg, who's patients and idea it was to evaluate the original 52 specimens.² Furthermore, the initial description of the condition was actually first made in 1769 by an Italian physician Giovanni Battista Morgagni – he of the anal columns, aortic sinus, and congenital diaphragmatic hernia fame.³ Much has changed since then, and continues to evolve in the understanding and treatment of this idiopathic, ulcerogenic, inflammatory condition of the gastrointestinal (GI) tract. Therefore, where many students and physicians alike are quick to cite Crohn facts such as its ability to occur anywhere along the alimentary tract, has no “curative” operation, and is hallmarked by periods of flares and quiescent disease, what is often forgotten is that three-quarters or more of all patients will require at least one operation during their lifetime.⁴ Therefore, not only must the problem at hand be addressed, but also the patient's future function should be carefully weighed when considering the proper therapeutic endeavor. Surgeons also need to be exceedingly aware of the indications, surgical options, and expected outcomes for patients with Crohn disease, as well as have a thorough understanding of the principles guiding both medical and surgical care to maximize outcomes. This chapter will review the pertinent information regarding the background, diagnostic evaluation, and treatment modalities for Crohn disease.

EPIDEMIOLOGY

Traditionally, Crohn disease is said to have a bimodal distribution with regard to age of onset, initially in the second and third decades, followed by a later, albeit smaller, peak in the sixth decade.⁵ More recently, systematic reviews have found an annual incidence of Crohn disease ranging from 20.2 per 100,000 person-years in North America and 12.7 per 100,000 person-years in Europe to 5.0 person-years in Asia and the Middle East.⁶ Even within regions, variations exist – the incidence in western Europe is almost twice that of eastern Europe, whereas the highest incidence of inflammatory bowel disease in

the world is in the Faroe Islands. While data in developing countries remain relatively sparse, both the incidence and prevalence of Crohn disease are increasing in the United States and around the world. There is also an association with latitude, with increased incidences in higher latitude areas (i.e., Canada, Scandinavia, and Australia) compared to those closer to the equator. Males and females tend to be affected equally, though whites and certain ethnic groups such as those of Ashkenazi Jewish descent have higher overall rates.⁷

Although Crohn disease is not inherited through traditional Mendelian genetics, there does appear to be a familial predisposition. A positive family history in patients with Crohn disease occurs in 2% to 14%.⁸ Closer examination reveals an approximate 5% age-adjusted lifetime risk of a first-degree relative of a Crohn disease proband developing IBD (up to 8% for those of Jewish ancestry).⁹ On the other hand, the concordance rate for monozygotic twins ranges from 20% to 50%,¹⁰ suggesting that genetics do play a role and that the disease is not entirely dependent on environmental and/or acquired factors. Furthermore, there does not appear to be a genetic concordance with regard to phenotypical manifestations (i.e., fibrostenotic, fistulizing, phlegmonous or extent of disease) among relatives.

ETIOLOGY

Despite tremendous progress in the overall understanding of the disease and advancements in the comprehension of the various phenotypical manifestations, the exact etiology of Crohn disease remains unknown. Most hypotheses suggest there involves interplay among the genetic makeup of the individual along with environmental, bacteriologic, immunologic, and epidemiologic factors that contribute to its development. Efforts in each of these areas continue in attempt to determine which are causative factors versus those that are simply associations.

Current theories revolve around the host–microbiome interaction, and the variable response that occurs along several pathways that may ultimately lead to the chronic inflammatory state seen in Crohn's.¹¹ In this model, intestinal microorganisms initiate an inappropriately regulated host immune response that results in a cascade of events ranging from altered permeability of the intestinal lumen to autoimmune “attacks” on several host organ systems.¹² The fecal and intestine mucosal bacterial make-up is also known to be altered in Crohn disease patients; however, it is unknown if this occurs as a result of the inflammatory process, or is itself a contributing factor to disease development.¹³ Proteomic and metagenomic evaluation of commensal and altered GI microbiota in Crohn patients indicates that there is an inappropriate pattern recognition with the microbiota serving as the driver of the disease pathogenesis.¹⁴

Beginning in 1996, linkage studies of the human genome have helped with the discovery of several IBD genes that signify patients who are susceptible to Crohn disease development.¹⁵ Most attention has revolved around the NOD2 (formerly CARD15) gene on chromosome 16, a region felt to be involved host interactions with bacterial lipopolysaccharide.¹⁶ Genetic differences in the pattern-recognition proteins for which NOD2 codes may lead to an impaired sensing and handling of bacteria by the immune system, disrupting the tenuous balance of normal tolerance versus initiating an incorrect immune response. Since then, genome-wide association studies have provided insight that polymorphisms in genes such as the ATG16L1 and IRGM play a role in autophagy in Crohn patients. This process involves the regulation of cell development and differentiation, senescence, and ultimately the inflammatory system response to what the body deems is normal and abnormal.¹⁷ In addition, other genes such as TLR4, HLA, and IRF5 are involved in the innate and adaptive immune system response seen in Crohn patients. Other causative immune factors have included overexpression and dysregulation of tumor necrosis factor, an imbalance between proinflammatory and anti-inflammatory cytokines, and an impaired mucosal susceptibility in sampling gut antigens.¹⁸ Combined, these all contribute to regulatory mechanisms that may be altered and play a role in Crohn disease pathogenesis.

Infectious theories also continue to exist,¹⁹ with specific organisms including *Mycobacterium avium* subspecies *paratuberculosis* (i.e., Johne disease), *Campylobacter concisus*, adherent-invasive *Escherichia coli* (AIEC), and non-*H. pylori* *Helicobacter* species among the most common agents cited. Although the beneficial effects of antibiotics in the treatment of Crohn disease provide indirect evidence for a bacterial etiology, no distinct organism has been identified to date. Similarly, several viruses have been postulated to have an association with Crohn disease, the most common being EBV, CMV, and measles. However, systematic reviews have found little evidence to support this notion.²⁰ Additionally, environmental factors are felt to play a role, highlighted by the well-established link to smoking with both an increased susceptibility and worsened clinical course. Finally, while patients with Crohn disease

frequently have concomitant food intolerances, the role of dietary habits remains debatable.²¹ Rather than a causative effect, it is felt that the microbiome in the human GI tract is heavily influenced by dietary intake, leading to a local environment ripe to foster susceptibility to Crohn disease.

DIAGNOSIS

As is well documented, Crohn disease falls under the umbrella of inflammatory bowel disease along with ulcerative colitis. In both conditions, there is no specific test at present to permit a definitive diagnosis; rather a combination of history and physical examination, laboratory, radiographic and endoscopic findings is utilized. This, in part, contributes to ~5% to 15% of patients with ulcerative colitis that will eventually be diagnosed with Crohn disease or patients who carry a diagnosis of indeterminate colitis.^{22,23} Once diagnosed, Crohn patients are often categorized in several different manners, the most common of which involves either the site of disease or the patient's phenotypical manifestations (i.e., fibrostenotic, fistulizing, inflammatory). By location, the ileum (~60%) has the highest rate of disease incidence (Fig. 50-1). Localized inflammation in the ileocecal region occurs in ~45% of patients, whereas ~25% to 33% will have colonic involvement, 25% will have more proximal small bowel disease, and <10% will have upper GI or perianal disease. In general, patients with concomitant perianal disease tend to have a more severe clinical course,²⁴ and perianal disease in the setting of Crohn's may precede abdominal manifestations in up to 45%.²⁵

When stratifying by disease pattern or phenotype, patients may have fibrostenotic (i.e., stricturing), fistulizing (i.e., penetrating), or inflammatory (i.e., phlegmonous) characteristics. Due to the heterogeneous nature of the disease, these manifestations may occur independently, concomitantly, or may even vary along the longitudinal course of the disease. Fibrostenotic patterns may occur in any location, though most commonly occur in the terminal ileal region, where patients present with obstructive-type symptoms such as nausea, vomiting, and decreased oral intake. Due to the recurrent chronic nature that results in progressive thickening of the bowel wall, medical management is typically unsuccessful and surgical intervention is required. Inflammatory disease may present with a wide range of symptoms such as abdominal pain, fever, and an abdominal mass and/or weight loss. Bowel movements may either be diarrhea or follow an obstructive pattern due to luminal narrowing or extrinsic compression from the phlegmon. Finally, penetrating or fistulizing disease also has a variable presentation. Patients may be completely asymptomatic, as in the case of many entero-enteral fistulas, present with anorectal abscesses and/or fistulas, or more commonly complain of symptoms mirroring involvement of the secondarily involved organ—recurrent urinary tract infections or pneumaturia, vaginal discharge, diarrhea, cutaneous feculent drainage, and/or hip/back pain from psoas involvement. While medical management continues to be a major component of each of the latter two patterns, surgery is often required for resolution of symptoms.

Figure 50-1. Terminal ileum with forceps pointing to intraloop chronic abscess cavity.

Clinical Evaluation

Small Bowel

The distribution of disease will in large part dictate the clinical presentation. The terminal ileum (along with the cecum) is the most commonly affected site, in addition to isolated more proximal small bowel disease. Patients with disease in this location will classically present with abdominal pain, fever,

fatigue, nausea, and vomiting. The weight loss seen is a byproduct of both decreased oral intake as well as the malabsorptive process associated with Crohn's. When the disease is in the terminal ileum and ileocecal region, patients may present with a slow onset of right lower quadrant pain following meals, an abdominal mass, and (when the psoas is involved) pain with hip extension. Obstructive symptoms may also occur in patients with either fibrostenotic or acute inflammation (Fig. 50-2). Diarrhea tends to be nonbloody, though heme-positive stools may occur, and rarely gross blood is a manifestation from a small bowel source.

Colonic

Colonic involvement may occur in isolation in approximately one in four patients, though it is most often seen concomitantly in those with perianal (left-sided) or terminal ileal (cecal and ascending colon) disease.²⁶ Within the colon the distribution is somewhat variable, with approximately one-third of patients having total colonic involvement, 40% showing segmental disease, and left-sided only in up to 30%.²⁷ Regardless of the exact location within the large intestine, patients with colonic involvement may experience abdominal pain, and in some cases, malnutrition. Diarrhea is often of smaller volume and may be from several sources – malabsorptive (e.g., salt/water and bile acid malabsorption), infectious (e.g., CMV super-infection), or as a result from an entero-colonic fistula.^{28,29} Unlike ulcerative colitis, rectal bleeding is not routine, and bowel movements are often nonbloody, except in those with moderate-to-severe Crohn colitis. In addition, similar to disease in the small bowel, patients can experience hip pain from fistulas, cramping and obstructive symptoms. Patients with chronic disease may also demonstrate pseudopolyps on endoscopic examination (Fig. 50-3).

Anorectal

Bissel³⁰ was the first to describe the anorectal component of Crohn, almost two years after the original description of the disease. Despite advances in the understanding of many features of Crohn disease, perianal complaints have been recognized as one of its most challenging aspects. Isolated perianal disease is the presenting symptom in ~5% to 15% of Crohn patients; though over the course of their lifetime, it is seen in 25% to 80%. The perianal area in Crohn patients has classically been felt to be a “window” into the abdomen, and perianal involvement is clearly more common in those with concomitant rectal or colonic disease.^{31,32} In addition, active disease in the perineum is felt to act as a harbinger of an overall more virulent course.³³ The traditional anorectal complaints witnessed in non-Crohn patients are similar to those with the disease, including “standard” hemorrhoids, fissures, abscesses and fistulae. However, Crohn patients may also manifest edematous (elephant ear) skin tags (Fig. 50-4), blue discoloration of the anus, and abscesses and fistulas that are often recurrent, multiple, and located well away from the anal verge. While fissures due to hypertonicity may be identified, more often Crohn fissures present as deep-seated, burrowing fissures – more like ulcers – and may be multiple, off the midline, extending in the muscle and associated with large skin tags. Finally, patients with long-standing Crohn's may develop anal stenosis or an anal stricture at the verge secondary to repeated bouts of chronic inflammation.

Figure 50-2. Endoscopic view of a terminal ileum stricture and active Crohn disease.

Figure 50-3. Endoscopic view of colonic pseudopolyps.

Figure 50-4. Anorectal Crohn disease. Large “elephant ear” skin tag.

Clinical evidence of perianal Crohn, as manifested by many of these features, is often deemed a hallmark of disease diagnosis, although occasionally a biopsy may be necessary. Due to local sepsis and perianal tenderness, patients may need to undergo an examination under anesthesia to fully identify the extent of the disease. Patients presenting with perianal findings consistent with Crohn disease should undergo a full alimentary tract evaluation, as previously stated, with endoscopic and radiologic evaluation. In addition, a thorough physical examination to identify any extraintestinal manifestations should be performed.

Upper Gastrointestinal Disease

Upper GI Crohn encompasses disease from the mouth through the jejunum. The incidence of upper tract involvement varies widely, with most studies reporting overall rates of $<5\%$. In patients with ileocolic disease, concomitant upper GI manifestations occur in 0.5% to 13%, yet up to 40% of patients will demonstrate early subclinical evidence of Crohn disease on radiologic and endoscopic evaluation.³⁴ Importantly, when patients have upper GI Crohn disease, they almost uniformly have concomitant disease of lower tract and should be evaluated to determine the extent of involvement. Upper tract disease is hallmarked by both obstructive symptoms and fistulas.³⁵ Patients typically present with abdominal pain, cramping, nausea, vomiting, or intolerance of oral intake leading to weight loss. While fistulas may be virtually to any site, the majority involving the proximal tract are gastrocolic or ileogastric in nature. Patients may be asymptomatic or present with diarrhea from high-output and colonic involvement. Crohn disease of the esophagus is exceedingly rare, involving $<0.5\%$ of patients. Most patients will have inflammation or ulcers, though strictures and fistula have also been reported. As with other upper tract Crohn disease, extra-esophageal disease is nearly always present.³⁶

Extra-Intestinal Disease

Similar to ulcerative colitis, patients with Crohn disease may have manifestations from the disease process that extend outside of the GI tract (Table 50-1). Extra-intestinal disease (EID) has been reported in ~6% to 47% of patients with inflammatory bowel disease, and has an increased concordance among siblings and first-degree relatives – suggesting a genetic component that has been linked to the major histocompatibility complex (MHC) on chromosome 6.^{37,38} EID occurs secondary to the systemic inflammatory process associated with the underlying disease and affect a wide range of organ systems. While the GI tract may be the primary source, the dysfunction in immune regulation incites a pathologic response that may occur in nearly every location in the body simultaneous with, preceding, or following GI manifestations.³⁹ Overall, rheumatologic/joint problems (e.g., peripheral or sacroiliac arthritis, arthralgias) are the most common, occurring in up to one-third of patients. Other more frequent sites of involvement include the skin (Fig. 50-5), eyes, and hepatobiliary system; while the renal, pulmonary, nervous, and coagulation systems are typically involved to a lesser extent. It is important to distinguish between manifestations that parallel bowel disease activity (episcleritis, peripheral arthritis, and erythema nodosum) from those that do not (ankylosing spondylitis, pyoderma gangrenosum, and primary sclerosing cholangitis). Surgical intervention directed at the bowel may occasionally be required for recalcitrant EID that may appropriately go into remission following bowel resection.⁴⁰

Table 50-1 Classification of Extra-intestinal Manifestations of Crohn Disease

Organ System	Extra-Intestinal Manifestations
Musculoskeletal	Arthralgias, peripheral arthritis, ankylosing spondylitis, sacroilitis
Ocular	Uveitis, iritis, episcleritis, conjunctivitis
Renal	Glomerulonephritis, amyloidosis
Skin/Mucocutaneous	Erythema nodosum, pyoderma gangrenosum, aphthous ulcers
Blood	Thromboembolic disease, hemolytic anemia
Pulmonary	Bronchitis, pleuritis, tracheal stenosis
Hepatobiliary	Hepatitis, primary sclerosing cholangitis, pancreatitis, cirrhosis
Cardiac	Pericarditis, myocarditis
Neurologic	Demyclinating disease, neuritis

Figure 50-5. Peristomal pyoderma gangrenosum. (Courtesy of W. Brian Sweeney, MD.)

Radiology

Fluoroscopic Imaging

Radiologic work-up for Crohn patients is an invaluable part of the diagnostic evaluation. In addition to providing information on the acute process (i.e., abscess, phlegmon, fistula, stricture), diagnostic imaging is used to determine the extent of disease. Historically, contrast studies such as a barium enema have helped diagnose Crohn disease by identifying longitudinal and transverse linear ulcerations that create cobblestone and nodular patterns, skip lesions, fistulas, and strictures.⁴¹ A small bowel follow-through has also been a long-standing modality utilized to evaluate for strictures, active disease (highlighted by ulceration, mucosal granularity, and loss of villous morphology), and fistulas (Fig. 50-

6).

Computed Tomography

In many centers, computed tomography (CT) has now largely replaced the barium enema and small bowel follow-through, with the added ability to identify the extent of the disease and involvement of surrounding structures, manifested by segmental bowel thickening (Fig. 50-7), mesenteric fat stranding, and intra-abdominal fluid.⁴² Additionally, CT is useful to identify secondarily involved organs or provide information that may be pertinent to preoperative planning, such as bladder or vaginal air indicating presence of a fistula, an adjacent psoas abscess in ileocecal disease, or ureteral obstruction that may require stenting. CT and magnetic resonance (MR) enterography provide improved detail of the mucosal surface and are especially useful in depicting fistulas and strictures, along with the added benefit of lower levels of radiation exposure. The latter is especially relevant considering the generally younger patient population, body habitus, and potential need for life-long repeat imaging associated with Crohn's.

Figure 50-6. Small bowel follow-through demonstrating a tight stricture with proximal dilation.

Figure 50-7. Coronal cut of a CT demonstrating a jejunal stricture.

Magnetic Resonance Imaging

MR enterography in particular has been shown to be over 85% accurate in predicting stenosis (Fig. 50-

8), abscess and fistula in preoperative planning, as well as changing the surgical strategy/approach in up to 10% of Crohn patients.⁴³ Furthermore, its sensitivity (85% to 90%), specificity (100%), and negative predictive value (77%) have made it ideal for detecting recurrent disease after surgery.^{44,45}

MRI has also particularly been useful in the evaluation of complex perianal fistulas seen in Crohn patients, identifying secondary “hidden” tracts and occult abscesses that lend to higher failure rates if not addressed.⁴⁶ More recently, diffusion-weighted imaging and magnetization transfer imaging sequences have allowed bowel resolution previously not achievable to help identify disease, depict disease activity, and target interventions.⁴⁷

PET Scan

Another modality typically not associated with inflammatory bowel disease, 18F-FDG positron emission tomography (PET) has been used for Crohn disease largely in academic and research centers to date.⁴⁸ While cost seems to be somewhat prohibitive, this emerging indication has the potential to (a) determine disease activity in a noninvasive manner, (b) provide information regarding subclinical disease, (c) deliver a qualitative measure of response to treatment, and (d) indicate disease activity that would otherwise be unobtainable by traditional methods.

Video Capsule Endoscopy

Finally, video capsule endoscopy uses wireless technology to capture continuous images of the upper GI tract mucosa. As up to 30% of patients will have disease limited to the small bowel, capsule endoscopy plays a unique role to determine disease presence and activity that are outside the reach of endoscopy and the limitations of traditional small bowel imaging. While the diagnostic yield may not be as high, it has been shown to be comparable to ileocolonoscopy and better than small bowel follow-through for the detection of small bowel inflammation.⁴⁹ Furthermore, negative predictive values range from 96% to 100%, essentially ruling out the diagnosis of Crohn’s when the results are normal.⁵⁰ Of note, it is imperative to exclude the presence of moderate–severe strictures prior to its use, as their presence can result in bowel obstruction from the capsule becoming lodged at the point of stenosis (Fig. 50-9).

Endoscopy

Whereas direct observation of the perianal area and anoscopy will identify disease such as skin tags, external fistula openings and fissures, endoscopy is needed to identify the extent and severity of the disease and perform biopsies to aid in diagnosis.⁵¹ In the clinic, flexible or rigid sigmoidoscopy can be performed as adjuncts to the physical examination to evaluate the mid-to-upper rectum and sigmoid colon. However, endoscopic evaluation of the entire colon, including the terminal ileum, with colonoscopy along with appropriate biopsies is required in patients suspected of Crohn disease. Early changes seen in the mucosa include aphthous ulcerations, erosions, and serpiginous ulcers that occur in a skip-type pattern. As the full-thickness inflammatory cycle continues, these ulcerated areas become progressive, enlarge, and coalesce forming the cobblestone-type pattern. The presence of rectal sparing and terminal ileal disease may help differentiate Crohn disease from ulcerative colitis, although the latter may demonstrate similar characteristics due to medical therapy and backwash ileitis, respectively.⁵² Finally, the presence of strictures or associated masses may indicate the need for surgical or therapeutic intervention.

Esophagogastroduodenoscopy (EGD) also plays a role for patients with suspected or known proximal disease and can identify ulcers, fistulas, and strictures that may be responsible for various upper GI symptoms (Fig. 50-10). In addition, EGD allows for therapeutic intervention such as dilation for those with gastric outlet obstruction.⁵³ Overall, both upper and lower endoscopies are relatively safe procedures with complications in IBD patients occurring in <5%,⁵⁴ and generally consist of bleeding – though perforation remains a very small risk of every endoscopic procedure. Additionally, endoscopic evaluation provides an ability to track and quantify disease activity by use of the scoring systems such as the Crohn disease endoscopic index of severity (CDEIS) or Simple Endoscopic Score for Crohn disease (SES-CD).⁵⁵

Pathology

Classically, the presence of noncaseating granulomas on pathologic examination is pathognomonic of Crohn disease. However, in reality they are only found in 25% to 42% of patients, and may simply be a marker of more virulent disease.⁵⁶ In addition, long-standing ulcerative colitis patients may occasionally show granulomas on biopsy.⁵⁷ Furthermore, granulomas may be present but are not typically demonstrated on the specimens that are taken with routine depth endoscopic biopsies, rather only visible on resected full-thickness specimens. Other histologic evidence of Crohn disease includes architectural distortion of the crypts (size, shape, and symmetry) (Fig. 50-11), ulcerations, pseudopolyps (Fig. 50-12), and skip areas – some of which may also be found in ulcerative colitis. Other discriminating features of Crohn’s include the potential for full-thickness involvement of the bowel wall, and the presence of “creeping fat,” where the mesenteric fat extends over the serosal surface of the bowel wall – “creeping” over the normally distinct mesenteric/bowel wall interface. Furthermore, gross pathologic examination of Crohn specimens may range from acutely inflamed, edematous, hyperemic bowel to thickened, fibrotic, and “woody.” Finally, the mesentery is classically thickened, with marked edema, friability and hypervascular in nature.

Laboratory Analysis

No single laboratory examination will provide a definitive diagnosis of Crohn disease; yet, there are tests available to help discriminate between Crohn's and other processes. Routine serum profiles such as perinuclear antineutrophil cytoplasmic antibodies (p-ANCA) and anti-Saccharomyces cerevisiae antibodies (ASCA) have traditionally been used to help differentiate Crohn disease from ulcerative colitis. The former is a known marker associated with ulcerative colitis, whereas elevated levels of ASCA are associated with Crohn disease. Unfortunately, only 30% to 50% of Crohn patients will test positive for ASCA, and up to 10% of healthy individuals will also have elevated serum levels.⁵⁸

C-reactive protein is a nonspecific marker for inflammation that has been useful in tracking disease activity and response to treatment. More recently, fecal biomarkers such as fecal calprotectin,⁵⁹ lactoferrin, and neopterin⁶⁰ are used to monitor intestinal inflammation, and have been shown to reliably correlate with disease activity and mucosal healing as measured endoscopically.⁶¹ In addition they may play a role in helping to make a distinction between inflammatory bowel disease and functional bowel disorders, with reported sensitivities and specificities of ~80% to 85%.⁶² While nonspecific, persistent elevations in fecal biomarkers have been shown also to correlate with higher levels of recurrence following surgical resection.⁶³

DIFFERENTIAL DIAGNOSIS

The differential diagnosis in Crohn disease is wide and includes both benign and malignant processes (Table 50-2). While Crohn disease has certain traits that are more suggestive of its presence (e.g., noncontiguous multisite disease, fistulas, creeping fat), a variety of abdominal process may mimic Crohn's (Fig. 50-13). It is not an uncommon scenario for ileocolic Crohn's to be ultimately diagnosed from a clinical picture that may at first resemble acute appendicitis, right-sided diverticulitis, an infectious process, or a perforated malignancy. Radiologic studies may demonstrate similar patterns of bowel inflammation, laboratory examination often shows elevated CRP and/or white blood cell counts

in each, and the patient demographics are routinely alike. When this occurs intraoperatively, a decision must then be made regarding whether or not to proceed with resection versus closure and medical management alone based on clinical findings. If a resection is performed, questions arise regarding the extent of resection such as whether or not to perform an ileocectomy versus appendectomy alone and what margins of resection are required for the situation at hand.

Table 50-2 Differential Diagnosis of Crohn Disease

■ Ulcerative colitis
■ <i>Clostridium difficile</i> infection
■ Acute appendicitis
■ Meckel diverticulitis
■ Diverticulitis (diverticular-associated colitis)
■ Infectious colitides (CMV, Yersinia, <i>E. coli</i> , Salmonella, etc.)
■ Ischemic colitis
■ Tuberculosis
■ Radiation enteritis
■ Behçet disease
■ Malignancy
■ Celiac sprue

When confronted with this situation in the operating room and Crohn’s is suspected, traditional teaching recommends performing an appendectomy if the cecum is normal, or to withhold on resection and undergo medical treatment only. Yet, there are data to support performing an ileocolic resection at the time of surgery, with one series reporting almost half of patients required no further surgery as a result of their Crohn disease, compared to 92% of those undergoing appendectomy only (65% within the next 3 years).⁶⁴ Hence early ileocolonic resection may be in the patient’s long-term best interests to avoid recurrent disease and repeated trips to the operating room.

When disease is isolated to the colon, the major differentiation involves distinguishing Crohn colitis from ulcerative colitis, though other infectious and inflammatory colitides remain in the differential. As previously noted, many of the same clinical and histopathologic traits are shared in both diseases, and contribute to the initial diagnostic dilemma, as well as those patients with indeterminate colitis or those that undergo a change in diagnosis from ulcerative colitis to Crohn’s. Ultimately it is the entire evaluation to include information taken from laboratory, pathologic, endoscopic, radiologic, and clinical examinations as outlined above that will help clarify the picture and aid in diagnosis.

TREATMENT

Medical Management

While an in-depth look regarding the medical management of Crohn disease is beyond the scope of this chapter, a few points are worth noting (Table 50-3). First, despite the spectrum of disease presentations, Crohn’s remains one hallmarked by inflammation (i.e., abdominal pain) and diarrhea. As such, supportive care to include antidiarrheals and antimotility agents, along with a bland diet, are good first-line approaches to provide symptomatic control. It is important to exclude the concomitant presence of “super-infections” such as cytomegalovirus or *Clostridium difficile* infection, as antimotility medications may result in the onset of toxic megacolon and a rapidly progressive clinical deterioration. Yet, simple over-the-counter, readily available medications such as loperamide, diphenoxylate, and bismuth, along with prescription medications such as codeine and tincture of opium often provide tremendous relief to

abdominal pain, cramping, and loose stools.

Crohn's has also been traditionally been called a "wasting disease," though increasing numbers of obese patients with Crohn's are observed. Despite this seeming paradox, nutritional support in both groups remains paramount. Ideally, preservation of oral feeding in any form is crucial for maintenance of the absorptive and protective mechanisms provided by the GI mucosal lumen villi and microvilli. However, when this is not possible, parenteral nutrition has become invaluable in preserving nutritional stores, aiding in maintenance of positive nitrogen balance, preventing weight loss and improving perioperative outcomes.⁶⁵ This must be weighed against the potential complications involved with intravenous routes to include infectious complications and thromboembolic events.

A tiered strategy for medical therapy is often utilized, taking into account the disease activity (flare vs. chronic), pattern (inflammatory vs. fistulizing vs. fibrotic) and location. Antibiotics and aminosalicylates are typically used in the induction and maintenance of remission, respectively, especially for those with mild-to-moderate disease. Antibiotics are also utilized for the treatment of an acute infection for both the abdominal and perianal locations, with metronidazole and fluoroquinolones among the most commonly used. In select cases, antibiotics can be given to patients with perianal disease including fistulas for maintenance of remission as well as decreasing pain. While the exact mechanism of action of antibiotics in Crohn disease is debated, by decreasing bacterial load and altering the bacterial milieu of the GI tract, disease activity is lessened.

Aminosalicylates (5-ASA) are traditionally used as first-line maintenance agents, and are generally well tolerated by patients. Depending on the predominant location of the disease, different moieties can be formulated to allow maximal drug concentration to be targeted at the appropriate site. 5-ASA compounds are not aspirin or nonsteroidal derivatives, though they do work to decrease proinflammatory mediators and function at the mucosal level with reduced systemic absorption. Similar to antibiotics, the mechanism of action in inflammatory bowel disease remains unclear, though levels of NF-KB, TNF, and interleukin-1 have all been shown to decrease, as well as inhibiting both B- and T-cell function.⁶⁶ Additionally, they can be used in the perioperative period without increasing the risk of postoperative complications. Overall, this class of medications has been shown to prevent disease flares and minimize Crohn disease activity index for patients with mild disease, though the results have been inconsistent with questionable clinical benefit.⁶⁷ However, at most they have little downside and there is some data to suggest a decrease in disease recurrence following resection.

Steroids remain a mainstay in the treatment of Crohn disease for both the induction and maintenance of remission. They are especially useful in the setting of disease flares, where a "burst" followed by a weaning strategy may allow some of the more well-tolerated medications to be initiated as a maintenance regimen. Purported advantages to steroids include their low cost, ability to give via the intravenous, oral and rectal routes, and the relative speed and efficacy that they are able to help achieve quiescent disease. On the downside, ~14% to 45% of patients will ultimately have steroid recalcitrant disease, requiring either an escalation of medical therapy or surgical resection. Additionally, the wide range of potential complications of steroids ranging from adrenal suppression, insulin resistance, ocular disease, and osteopenia to psychosis, acne and weight gain, limits durable sustained use considerably. Budesonide is a synthetic corticosteroid that is taken orally or rectally, and the steroid effect is predominantly local due to a significant first-pass metabolism in the liver. While pooled analysis demonstrated inferior effects compared to systemic steroids, it has been shown to maintain rates of remission higher than placebo and comparable to prednisolone for those with mild disease.⁶⁸

Table 50-3 Medical Treatment for Crohn Disease

Class of Medication	Examples	Role in Therapy
Steroids	Prednisone Prednisolone Methylprednisolone Budesonide ^a	Induction of remission
Immunomodulators	6-Mercaptopurine Methotrexate Azathioprine Tacrolimus Cyclosporine ^b	Maintenance of remission Induction in select cases
5-ASA	Sulfasalazine Pentasa Mesalamine Olsalazine	Maintenance of remission in mild cases
Biologics	Infliximab Adalimumab Certolizumab Natalizumab	Induction and maintenance of remission
Antibiotics	Metronidazole	Induction of remission Treatment of infection

^aBudesonide is taken enterally and has only topical effect, no systemic effect.

^bCyclosporine can be used as rescue therapy/induction in refractory cases, but has not been supported by evidence in the treatment of Crohn disease.

The immunomodulator class of medications includes 6-mercaptopurine, azathioprine, methotrexate, tacrolimus, and cyclosporine. They work via different mechanisms of action, yet all serve a common purpose to alter the immune system in some capacity to blunt the patient's intrinsic response to what is considered "foreign" and to decrease inflammation. The first two (thiopurines) act via inhibition of purine synthesis, and must be monitored, as metabolites can lead to bone marrow suppression and hepatotoxicity. These drugs are useful for both the induction and maintenance of remission and particularly helpful in dose reduction and weaning patients off prednisone.⁶⁹ They also have a longer onset of action, and may take months until the full effect of the medication is witnessed. Methotrexate inhibits dihydrofolate reductase, also inhibiting purine and pyrimidine synthesis, and ultimately cytokine production. Its effects are better demonstrated with intramuscular or subcutaneous injection compared to oral, where both induction and remission rates are significantly worse.⁷⁰ Side effects range from blood dyscrasias and secondary malignancies to pneumonitis and hepatic fibrosis, and serial monitoring of liver function tests is recommended.

The comparatively new group of medications are the biologic agents such as infliximab, adalimumab, and certolizumab, which are monoclonal antibodies targeting tumor necrosis factor- α . They are also administered via subcutaneous or intravenous injection, with dosing intervals dependent on the patient response. Adalimumab is a fully human monoclonal antibody, and while still possible, provides the advantage of being less likely to develop drug antibodies than infliximab.⁷¹ Together they are extremely useful in the induction of remission, and more and more are utilized as first-line therapy for moderate-to-severe disease (especially those with fistulizing disease), as well as in the maintenance of remission for medically refractory patients. Several large-scale multicenter randomized trials including CLASSIC I and II, CHARM, PRECiSE-1, and WELCOME have all demonstrated not only their collective efficacy, but also the ability to induce and maintain remission in patients who had previously lost response to one of the others.⁷² They are not without reported significant side effects, however, including anaphylaxis, secondary malignancies, and opportunistic infections. Patients should be tested for latent tuberculosis prior to their administration to avoid resurgence. Additionally there is considerable debate in the literature as to their impact on perioperative complications and anastomotic leaks, with large center studies reporting contradictory results, and pooled analysis demonstrating a nonsignificant trend toward increased total complications (OR 1.72; 95% CI 0.93 to 3.19).⁷³ Despite this controversy, discretion may warrant consideration for diversion when these medications are used in the setting of higher-risk anastomoses.

Operative Management

Indications for Surgery

2 One of the basic tenets in the management of Crohn disease is that surgery is typically reserved either for failure of medical therapy (i.e., intractable disease or steroid dependency) or complications from the disease. Failure of medical management is still the most common reason for surgery in patients with Crohn disease, especially in colonic disease. Complications resulting in a potential need for operative intervention include fistula, abscess, obstruction (stricture), growth retardation, perforation, EID, bleeding, and malignancy. Of note, hemorrhage in Crohn disease tends to be a more rare event, and is

more commonly seen in ulcerative colitis or diverticular disease. Each of these will be outlined in the following sections. Despite improvements in medical therapy, over 70% of all Crohn patients will require surgery at some point in their lives, with almost half of those undergoing one operation requiring additional procedures. Therefore, having a firm understanding of the general principles and technical specifics is important to surgeons who care for these patients.

General Principles

3 While Crohn disease can affect the entire GI tract from mouth to anus, certain overriding principles can help guide the planning and operative management. First, Crohn disease is a process marked by lifelong potential for recurrence; therefore, preservation of bowel when possible and consideration of future function are paramount concerns during the planning phase.⁷⁴ Next, the extent of resection required is dependent on multiple factors, including location and duration of disease, ability to exclude malignancy, and prior resections that may have resulted in shortened small bowel. In addition, as the stools tend to be loose, consideration must be given to rectal compliance and sphincter function during surgical planning to avoid a “perineal colostomy,” whereby incontinuity management is preserved but the patient has no control. Furthermore, unlike ulcerative colitis, segmental resection for both small and large bowel is common with ileocolonic, colo-colonic, and rectal anastomoses all playing a role in avoiding a permanent stoma while maximizing functional bowel.⁷⁵ Crohn patients with pancolitis may undergo a total abdominal colectomy with ileorectal anastomosis (for those with rectal-sparing) or total proctocolectomy with end ileostomy.⁷⁶ Total proctocolectomy with ileal pouch-anal anastomosis is typically discouraged, and is normally the result of an initial misdiagnosis of ulcerative colitis.

4 Technical tips also come into play when planning for Crohn resections. For example, when performing a proctectomy, it is important to consider the potential for a delayed or nonhealed perineal wound. An intersphincteric dissection, which maximizes the amount of healthy muscle/tissue remaining, facilitates closure in attempt to avoid this complication. Some patients will require more extensive procedures such as flaps that utilize adjacent tissues (i.e., gracilis, bulbocavernosus), and may require plastic surgeon involvement.⁷⁷ In addition, as in the small bowel, length of resection margins does not influence the risk of relapse with segmental resections, and only grossly normal bowel is all that is required.⁷⁸ Finally, diversion may be more commonly used due to both the presence of active disease as well as the potential negative healing effects of the Crohn medications.

ABDOMINAL FISTULAS

Intra-abdominal fistulas may arise from either the small or large bowel and affect nearly every adjacent structure. Similar to any fistula, it is important to determine the site of origin of the fistula, as this section of bowel will typically require a formal resection when symptomatic (Fig. 50-14). On the other hand, a section of bowel may simply be involved in the process secondarily as a “bystander,” and the preferred treatment is to take the fistula down and primarily repair the site. It is important to ensure there is no significant active disease at the closure site, as this may predispose to healing problems and a subsequent leak. In this case, the preferred strategy would be to perform a segmental resection.⁷⁹ Transmural bowel inflammation and communication can also occur more commonly with the skin, bladder, or vagina. Once again, the bowel is the offending organ and should be resected, while ligation of the fistula and closure of the secondarily involved organ is adequate treatment. In certain cases, the inflammatory process is so intense, or there is a concern for concomitant malignancy, that the entire process should be resected en bloc. When an abscess is present, it is often preferable to percutaneously drain the abscess and ensure adequate medical therapy (that often includes biologics), prior to embarking on abdominal exploration.⁸⁰ Finally, asymptomatic entero-enteric or entero-colonic fistulas are often best left alone and treated medically, especially with the relative success of anti-TNF agents.⁸¹

Figure 50-14. Entero-enteric-colonic fistula.

OBSTRUCTION AND STRICTURE

Strictures in Crohn disease most commonly occur in the terminal ileum, but may arise anywhere along the GI tract (Fig. 50-15). Due to the transmural inflammation, it is not uncommon to have luminal narrowing within the bowel especially with repeated flares. However, the underlying pathophysiology may be from a phlegmonous/inflammatory process or secondary to the fibrostenotic pattern of disease. In the former, medical management may be successful, decreasing the inflammation and resolving the intrinsic or extrinsic “compression” on the bowel wall. On the other hand, patients with fibrotic strictures typically have little to no response to medical management (including anti-TNF agents) and most often require surgery.⁸²⁻⁸⁴ Emerging evidence suggests early treatment of strictures with aggressive biologic therapy may aid in preventing the onset of fibrosis, especially in patients under 40, prior to the onset of the irreversible cascade of fibrosis where surgery becomes inevitable.⁸⁵

Figure 50-15. Endoscopic balloon passing through the ileocecal valve to dilate a stricture.

Strictures also differ somewhat based on their location. The rate of colonic strictures has been reported to be as high as 7% to 17%.⁸⁶ In general, these benign strictures are responsive to medical management as well as endoscopic dilation for moderate-to-high-grade stenosis. Complicating the situation, malignancy has been shown to be present in ~7% of all colonic strictures,⁸⁷ and Crohn disease carries an increased risk of colorectal cancer above the general population. Furthermore, it is very difficult to differentiate malignant from benign strictures on strictly clinical basis. Therefore all colonic strictures should undergo endoscopic evaluation and biopsy. If malignancy is detected (or the lesion appears worrisome and remains indeterminate on work-up), a standard oncologic resection should normally be performed. For those that are clearly benign and nonresponsive to medical management, endoscopic dilation has been shown to provide symptomatic relief. Technical success occurs in ~70% to 90%, and provides initial symptomatic resolution in over 80% of patients.⁸⁸ Unfortunately, most patients with colonic strictures require repeated dilations. The procedure is generally safe, with hemorrhage and perforation occurring in <5%, and most often occur when balloon sizes over 25 mm are used. Although concomitant direct injection of the stricture with steroids or treatment with systemic steroids immediately after dilation have both demonstrated some success in

case series, the true effect of this remains uncertain.

Strictures of the small bowel have been reported in 20% to 40% of Crohn patients.⁸⁹ Treatment typically consists of medical management, though depending on the severity, many patients will require intervention. Small bowel strictures are often amenable to dilation via double-balloon enteroscopy, especially in the 10- to 20-mm range, though perforation is a known risk.^{90,91} Symptomatic relief occurs in ~75% to 90% following the first dilation, while approximately 30% to 40% will require repeated intervention over the next 3 years. For those with initial success, the cumulative dilation-free rate at 3 years is ~40% to 50%.⁹² Overall complications occur in ~10% to 15% (<5% major complications), and include pain, fistula, fevers, bleeding, and perforation.⁹³ Despite this success, many will require operative intervention when symptoms fail to resolve, repeated bouts occur, or when a stricture is associated with a nonresolving inflammatory process, malnutrition, immunosuppression or fistula. Options then include strictureplasty (see below) or resection.

Strictureplasty preserves bowel length by avoiding resection altogether. The Heineke–Mikulicz method involves a longitudinal incision along the antimesenteric border of the bowel with a transverse closure, and is useful for shorter segments of bowel. Additional techniques include the Finney strictureplasty, classically used for longer strictures of 7 to 15 cm in length, where the diseased segment is opened longitudinally, the bowel is folded upon itself, and a full-thickness anastomosis is formed. In another method, an isoperistaltic strictureplasty is constructed such that the narrowed diseased portion of the bowel is anastomosed to the dilated segment of an adjacent loop in a side-to-side manner. Complications have been reported in 4% to 15% in large series, and include obstruction, bleeding, sepsis, perforation, and death.^{94,95} Overall, 5-year recurrence rates for strictureplasty in jejunoileal and ileocolonic locations have been reported between 25% and 30%, including an ~3% site-specific recurrence. Similar to endoscopic dilation, malnutrition, presence of a phlegmon/perforation/fistula at the site, multiple strictures within a small segment, and suspicion of a malignancy are all contraindications to strictureplasty.⁹⁶

Strictures at prior anastomotic sites may occur from recurrent disease or secondary to technical problems. They are often amenable to dilation,⁹⁷ yet they are often fibrotic in nature and nonresponsive, thus requiring resection for symptomatic strictures. To prevent this, evidence from systematic reviews and meta-analyses suggests that side-to-side stapled anastomoses in Crohn patients undergoing an ileocolonic resection have a decreased rate of postoperative complications (OR = 0.54), leak (OR = 0.45), recurrent (OR = 0.2), and reoperation (OR = 0.18) when compared to hand-sewn end-to-end anastomoses.^{98,99}

MALIGNANCY

5 Historically, the risk of malignancy with Crohn disease was felt to be only slightly higher than the general population and significantly lower than the risk of patients with ulcerative colitis.¹⁰⁰ More recently, population-based data suggest that the cancer risk with long-standing Crohn's is ~4- to 20-fold above that of the average population, and equivalent to patients with ulcerative colitis. Known risk factors for malignancy include pancolitis (at least one-third) and a disease duration of >8 years.^{101–103} Endoscopic surveillance strategies to detect malignancy have had to date mixed results.¹⁰⁴ Data from a large meta-analysis found that surveillance colonoscopy has not shown to effect survival in these patients, though lesions are typically detected earlier.^{105,106}

The optimal surveillance strategy for patients with Crohn disease has not been determined. As such, most recommendations favor mimicking surveillance for ulcerative colitis in patients with Crohn colitis. In this algorithm, surveillance colonoscopy begins 8 years after disease onset for pancolitis and 15 years for patients with left-sided disease, and is repeated every 1 to 2 years. In addition, the American Society for GI Endoscopy, American College of Gastroenterology, and American Gastroenterological Association were unable to draw conclusions regarding the benefit or need to perform random surveillance biopsies.^{107–109} Treatment for malignancy in the Crohn patient is similar to that of the general population, with resection following standard oncologic principles. As synchronous and metachronous lesions have been reported in up to 10%, consideration should be given to a subtotal colectomy with ileorectal anastomosis in the absence of rectal lesions.

While most evidence is from patients with ulcerative colitis, a polyp in a setting of colitis (nonadenoma dysplasia-associated lesion or mass-DALM) has traditionally felt to carry a significant risk of malignancy and is a strong indication for a formal resection.^{101,110–113} While these nonadenoma-like

DALMs should typically undergo a colectomy, more recent evidence suggests that complete endoscopic excision of an adenoma-like DALM (i.e., a sporadic adenoma occurring in a patient with colitis with or without active disease) may be safely undergo a surveillance protocol.¹¹⁴ Low-grade dysplasia outside the setting of a nonadenoma-like DALM, and even in areas flat mucosa, warrants close follow-up, although the need for follow-up resection remains unproven.^{101,113}

HEMORRHAGE

Patients with Crohn may complain of bloody stools, however, frank hemorrhage in Crohn disease is fairly uncommon. Possible sources include deep ulcerations, toxic colitis, an underlying mass, or concomitant diverticular bleed. Significant upper GI bleeding is also rare, and likely from a secondary source other than Crohn's (e.g., ulcer, varices, esophageal tear, malignancy). Similar to any other patient with a significant GI hemorrhage, patients require continued resuscitation, correction of any coagulopathy, and transfusion as indicated. Adjunctive measures such as intravascular vasopressin and infliximab have also been described,^{115,116} though should not be considered first-line agents. Endoscopy is the most useful diagnostic and therapeutic maneuver for bleeding from either an upper or lower source. When endoscopy or medical therapy is unsuccessful or bleeding recurs, segmental resection is preferred when the source is localized in the large or small bowel. In the setting of unlocalized disease, every effort should be made to identify the source of bleeding, including upper and lower endoscopies, nuclear medicine scans, angiography, and small bowel evaluation (push endoscopy, video capsule endoscopy, or small bowel follow-through). However in the unstable or nonlocalizable lower source, a subtotal colectomy with end ileostomy may be required.¹¹⁷ In the case of upper GI bleeding, the source may be localized and controlled with endoscopy or may require a resection or ligation as in patients without Crohn disease depending on the underlying pathology.

SPECIFIC CONSIDERATIONS

Gastroduodenal Disease

As stated, gastroduodenal disease occurs in 0.5% to 4% of all Crohn patients. The most common indications likely to require advanced or surgical intervention involve stricture/obstruction, fistula or bleeding. Isolated gastric disease is even more rare,¹¹⁸ as the stomach will hardly ever be the sole source for the patient's complaints. It is important to exclude *H. pylori* infection, gastritis (NSAIDs), ulcers, and malignancy in the absence of disease elsewhere in the GI tract. Most patients will respond to medical management, especially with the anti-TNF- α therapy.¹¹⁹ Gastric outlet obstruction at the level of the pylorus and first portion of the duodenum is often amenable to endoscopic balloon dilation, with avoidance of surgery in approximately half of patients.¹²⁰

Duodenal strictures are more frequent with disease in this location, and case series have demonstrated successful amelioration of symptoms with endoscopic dilation.¹²¹ More often, symptomatic duodenal strictures nonresponsive to medical therapy will be managed by strictureplasty, resection, or to a lesser extent, bypass (i.e., gastrojejunostomy). As previously noted, the type of strictureplasty will depend on the location, status of the surrounding tissues (i.e., ability to mobilize), and length of the stricture.¹²² Fistulas typically arise from disease located more distally in the small bowel, and therefore require resection of the primary site with closure of the stomach or duodenum. Occasionally the upper tract is the original of the fistula and resection or bypass is required. With appropriate expertise, a laparoscopic approach has been associated with fewer complications and improved recovery. If bypass is performed, vagotomy is not needed; however, every effort should be made to avoid bypass if possible, as this is associated with worsening diarrhea and nutritional abnormalities.¹²³ For those cases where resection or closure of the duodenum is required, a jejunal serosal patch or Roux-en-Y duodenojejunostomy may help minimizing wound breakdown and recurrent fistulas.¹²⁴

Small Bowel Disease

Most small bowel disease is amenable to surgical resection and primary anastomosis. As stated, strictureplasty is another option for those patients with short bowel, multiple sites of noncontiguous disease, and early recurrence – especially for those with noninflammatory patterns. Following resection, consideration should be given to the nutritional status of the patient, medications, and overall

physiologic state, as diverting stoma may be required to minimize the incidence and consequences of an anastomotic leak. A minimally invasive approach, similar to other disease states, has been associated with improved short-term outcomes in Crohn patients including decreased morbidity, shorter length of stay, and reduced hospital charges for both primary and recurrent diseases.¹²⁵ In addition, despite some contradictory evidence, laparoscopy and open approaches appear to have similar long-term rates of disease recurrence.¹²⁶

Bypass is rarely performed for small bowel disease. The rare case of a septic, obstructed patient with a large terminal ileum/ascending colon phlegmon involving the retroperitoneum that does not allow for safe mobilization or identification of the ureter and vascular anatomy may be one indication where bypass could still prove useful. These procedures have largely been abandoned as the underlying inflammatory process remains and has not been adequately addressed. Therefore, resection and strictureplasty continue to be the primary modalities to approach small bowel disease.

The mesentery in active Crohn disease always presents a particular challenge for surgeons. Due to its thick, edematous nature with increased neovascularization, adequate hemostasis is always a point of concern. Safe division in the era of open surgery involved techniques such as overlapping clamps with both mass and individual vessel suture ligation, where appropriate. Laparoscopic approaches typically rely on advanced vessel sealing devices for hemostasis, though they may be inadequate in the Crohn patient. Surgeons must then rely on other means such as placing an ENDLOOP (Ethicon, Cincinnati, OH) on the major vessels or intracorporeal suturing. Crucial to whatever method is used is the notion to avoid mesenteric hematomas, as these may result in continued bleeding as well compromise the blood supply to the healthy remaining bowel.

Colorectal Conditions

Toxic Colitis

Toxic colitis may occur in Crohn patients similar to those with ulcerative colitis.¹²⁷ Following resuscitation and intravenous steroids or immunosuppressants, emergent surgical intervention is often required for those with recalcitrant disease, perforation, or a deteriorating clinical state. The operative procedure of choice is a subtotal colectomy with end-ileostomy. Debate exists as to the handling of the rectal stump, though options include a distal mucus fistula with remnant sigmoid, implantation into the subcutaneous space, or local reinforcement of the stump. Proctocolectomy should be avoided in this situation due to the prolonged operative time and increased risk of morbidity and mortality.

Table 50-4 Perioperative Complications of Bowel Resection in Crohn Patientsa

Complication	Incidence
■ Bleeding	■ 1–5%
■ Anastomotic leak	■ 1.3–17% ^b
■ Anastomotic stricture	■ 6–13%
■ Anastomotic recurrence of disease	■ 15–39%
■ Bowel obstruction/ileus	■ 5–23%
■ Abscess/intra-abdominal sepsis (excluding leak)	■ 2.1–15%
■ Wound infection	■ 10–33%
■ Thromboembolic	■ 1.4–3.3%

^aRisk factors: malnutrition, obesity, emergent surgery, immunosuppressant use, smoking, older age, open approach, stoma surgery.
^bDepending on location and definition (clinical vs. radiologic).

Ileo-Anal Pouch

Ileo-anal pouch in the patient with Crohn disease most commonly occurs in the setting of an initial “mis”diagnosis of ulcerative colitis. More often to the point, the pouch is performed, and the patient will manifest Crohn disease at a later stage. While certain expert centers may advocate total proctocolectomy and ileal pouch construction for highly select patients with Crohn disease¹²⁸, in general, this is to be discouraged. Retrospective studies have reported 35% to 93% of patients will have Crohn’s-related complications such as pouchitis, abscesses, and pouch-anal fistulas, with another 10% requiring pouch excision or permanent diversion. Furthermore, roughly half of patients will experience urgency or continence issues. Of those patients with a functioning pouch, over half will continue to require medication to treat active Crohn disease^{86,129,130} (Table 50-4).

Treatment of Anorectal Conditions

6 A distinguishing characteristic of the surgical treatment for anorectal Crohn disease is to first consider whether or not they are symptomatic (see Algorithm 50-1). As a follow-on principle, aggressive intervention in the asymptomatic patient is unwarranted and potentially dangerous.

Algorithm 50-1. Crohn disease with anal complaints.

Algorithm 50-2. Anal skin tags in Crohn disease.

Specific Clinical Disease Processes

Anal Skin Tags and Hemorrhoids

7 Crohn patients often suffer from skin tags that appear as large, edematous, and blue colored (see Algorithms 50-2 and 50-3). Similarly, they may also suffer from internal and external hemorrhoids that may bleed, prolapsed, and cause difficulty with hygiene and irritation. It is important to keep in mind that Crohn patients have the propensity for poor healing, especially in the face of diarrhea. Patients should be counseled as to the risk of nonhealing wounds, continence problems, and mucus drainage.¹³¹ Therefore, at least an initial attempt at conservative treatment with warm sitz baths and control of diarrhea is warranted. During this time, medical therapy toward Crohn should be also optimized, as active inflammation/proctitis will lead to increased morbidity. Should a conservative route fail, standard hemorrhoidectomy may be performed (in the absence of active proctitis). Topical metronidazole has been shown to improve posthemorrhoidectomy pain as well as improve healing, with very little downside.¹³² Finally, although internal hemorrhoids may occur as in any other patient, they tend to be less symptomatic and often respond to conservative measures.

Anorectal Abscess/Fistula

Treatment of anorectal abscesses in the setting of Crohn is essentially no different than those of

cryptoglandular origin – incision and drainage (see [Algorithm 50-4](#)). Crohn patients may have more extensive disease, and adjunct radiology testing may be useful, especially when the examination does not match the patient’s symptoms. From a technical standpoint, it is important to place the incision as close to the anal verge as possible while still achieving adequate drainage, considering the possibility of fistula development.¹³³ Alternatively, a small pessar mushroom tipped catheter may be placed in the cavity, thus evacuating the abscess and allowing the cavity to close around the catheter, while allowing continued drainage.

Algorithm 50-3. Hemorrhoids in Crohn disease.

Algorithm 50-4. Anal abscess/fistula in Crohn disease.

Perianal fistulas are often deep, eroding through sphincter and occur in the setting of extensive scarring around the sphincter. Moreover, they can have high blind tracts, originate at levels well above the dentate line and are often found in conjunction with active proctitis. Determining the anatomy of the tract is required, but attention should also be given to the presence or absence of proctitis, status of the sphincter, prior anal operations, and potential for chronic diarrhea (i.e., medically controlled or not). Aggressive fistulotomies must be avoided. Yet, low-lying fistulas in the absence of overt proctitis can often be treated safely with fistulotomy.¹³⁴ When the fistula is higher or more complex, endoanal advancement flaps, fistula plugs, or the LIFT procedure (ligation of the intersphincteric fistula tract)

may all be performed with varying rates of success. Many patients with fistulous disease require chronic indwelling setons such as silastic vessel loops. Patients should be periodically reexamined both to ensure that there is adequate drainage, as well as to look for a potential malignant growth, with case reports of squamous cell and adenocarcinoma arising in a fistulous tract (Fig. 50-16). Unfortunately, fistulas and fistula procedures all vary in their outcomes, with healing rates ranging from 15% to 97% and morbidity rates 3% to 78%, making it difficult to accurately compare results. As such, consideration should be given for a diverting stoma for recurrent or complex fistulas. Finally, a small percentage of patients may require permanent diversion or even proctectomy.¹³⁵

Rectovaginal/Anovaginal Fistula

Rectovaginal fistulas are particularly problematic in Crohn patients (Fig. 50-17). Because many of these fistulas are associated with a deeply erosive process and intense inflammation, extensive tracts and hidden associated abscesses may also be present. In addition, a rectovaginal fistula may originate from small bowel, thus limiting potential diagnostic methods such as the methylene blue enema. Many patients require diversion in this setting prior to any definitive repair to aid with control of proctitis and to optimize the conditions needed for successful healing. First-line options include use of the fistula plug, endorectal advancement flap, and LIFT procedure.¹³⁶ Due to the complexity of the wounds and need for healthy tissue interposition, muscle flaps (e.g., gracilis, bulbocavernosus) are especially useful, and may require a multidisciplinary team.

Figure 50-16. Adenocarcinoma arising out of a chronic fistula tract in a Crohn patient. (Courtesy of Howard Ross, MD.)

Figure 50-17. Rectovaginal fistula in a Crohn patient.

Anal Fissure

Patients with Crohn disease and anal fissures present a particular challenge. Decreasing the continence in any way may worsen an already difficult clinical situation, and limit the number of patients that may successfully undergo surgery (see Algorithm 50-5). Despite an appearance that is hallmarked by deep, burrowing, off the midline and sometimes multiple wounds (Fig. 50-18), many anal fissures are fortunately painless and require no intervention. Excessive pain should raise the suspicion for an underlying abscess and prompt an examination under anesthesia. Initial attempts at conservative therapy with topical metronidazole, smooth muscle relaxants and local anesthetics may be attempted to palliate symptoms and help with healing.¹³⁷ For particularly symptomatic fissures, botulinum toxin has

also been used. In contrast, other authors have advocated a more aggressive surgical approach in Crohn patients, with one report citing 67% of patients who were treated surgically ultimately healed.¹³⁸ Yet, given the continence risks associated with surgery, medical management is the preferred initial therapy in patients with Crohn-related fissures. Surgical intervention should be reserved for those patients with minimal active anorectal inflammation who fail all reasonable conservative therapy, and still sphincter muscle division should be kept to a minimum.

Figure 50-18. Crohn fissure – notice the deep burrowing nature off the midline with signs of old fistula tracts.

Algorithm 50-5. Anal fissure in Crohn disease.

Algorithm 50-6

Algorithm 50-6. Anal stenosis/stricture and Crohn disease.

Anal Stenosis and Ulcer

Anal ulcers, stenosis, and strictures secondary to Crohn, while uncommon, can be extremely debilitating (see [Algorithm 50-6](#)). Single institutional series have demonstrated success rates of biologic agents in 18% to 60%.^{139,140} Up to one-third of patients will have concomitant abscess or fistulas, and these should be appropriately drained. Due to the association of chronic inflammation with the development of malignancy, biopsy of any suspicious lesions should also be performed. For low-grade strictures, anal dilation has proven successful, though repeated session is the norm. Other options include steroid injection or biologics, balloon dilation, strictureplasty, flaps, and even proctectomy – depending on the severity and response to therapy.¹⁴¹

Anorectal Malignancy

Anorectal cancer may occur in any setting, including Crohn disease. Risk factors in patients with Crohn disease include the presence of chronic inflammation, long-standing open wounds, and use of immunosuppressant medication. Both squamous cell carcinoma (Marjolin ulcer), adenocarcinoma, and their variants may occur.¹⁴² Patients (especially those with long-term indwelling setons) should be periodically examined to exclude the presence of malignancy. All suspicious lesions should undergo biopsy and any malignancy identified should undergo proper staging and treatment.

SUMMARY

Crohn disease remains a complex disease process with many different manifestations in the GI tract. Although advances in medical therapy continue to evolve and significantly alter the way patients are managed, surgeons still play a large role in both the medical and surgical therapies of the disease. Due to its recurring nature, surgeons must adhere to the principles of preventing and managing disease complications versus aiming for cure. By focusing on the maximization of functional outcomes, surgeons can optimize outcomes through a multimodality approach and minimize additional complications.

Chapter 51

Small Bowel Tumors

Steven G. Leeds and James W. Fleshman

Key Points

- 1 The main types of primary small bowel tumors include adenoma, adenocarcinoma, neuroendocrine (carcinoid), lymphoma, and sarcoma (GIST). Surgical resection remains the treatment of choice for all except lymphoma (only needed for symptomatic lesions causing obstruction or bleeding).
 - 2 There is a rising incidence of small bowel tumors, directly caused by a relative increase in the incidence of carcinoid tumors over adenocarcinoma of the small bowel. This trend is occurring globally.
 - 3 Research is now focused on the molecular cause of the discrepancy between the number of small bowel and colorectal adenocarcinomas.
 - 4 Size and location influence the symptoms caused by tumors within the small bowel. The majority of tumors found incidentally are asymptomatic.
 - 5 Capsule endoscopy (CE) is helpful for diagnosis but lack of spatial orientation, inability to biopsy, and capsule retention causing obstruction limit its usefulness. Small bowel enteroscopy, device-assisted enteroscopy (DAE), or deep enteroscopy (DE), are excellent alternative modalities.
 - 6 Even though small neuroendocrine tumors (NETs) can metastasize, the risk of metastasis correlates with the size of the primary tumor.
 - 7 There are three common radiographic modalities used to diagnose small bowel tumors which include CT scan, MRI and CT, or MR enterography. NETs also benefit from octreotide scanning as a functional scan to detect metastasis.
 - 8 Chromogranin A tends to be the most sensitive indicator of recurrence during surveillance of NET, and sensitivity and specificity depends on the functionality of the tumor.
 - 9 Gastrointestinal stromal tumors (GISTs) arise from pacemaker cells (Interstitial cells of Cajal) of the small intestine and, based on mutations in the c-kit proto-oncogene region of the tyrosine kinase gene, respond to imatinib (tyrosine kinase inhibitor) monoclonal antibody. Surgical resection remains the only curative method of treatment.
 - 10 Melanoma is the most common extraintestinal malignancy with predilection to metastasize to the small bowel.
-

INTRODUCTION

1 The small bowel can give rise to both malignant and benign neoplasms. It comprises about 75% of the entire length of the gastrointestinal tract and provides about 90% of its mucosal surface area, but surprisingly these neoplasms represent less than 5% of the cancer affecting the entire gastrointestinal tract.¹ Even so, small bowel cancer causes significant morbidity and mortality because of its potential to metastasize and to invade critical structures in the abdomen and retroperitoneum. The main types of malignancy include adenocarcinoma, neuroendocrine (carcinoid), lymphoma, and sarcoma (GIST). Several benign neoplasms such as lipomas, hamartomas, leiomyomas, and desmoid tumors are found in the small intestines. Recent large database queries have demonstrated that the most common malignancy is now carcinoid. Adenocarcinoma formerly was the most common, but the rising incidence of carcinoid tumors has recently surpassed it.^{2,3} The relative inaccessibility of the small bowel endoscopically presents several difficulties in diagnosis, results in a delay in diagnosis, and yields advanced disease or metastatic disease at the time of treatment. There is some utility for upper endoscopy (EGD), but the progress in Pillcam endoscopy and small bowel enteroscopy has improved the ability to diagnose, and possibly treat, these neoplasms. Exploratory laparoscopy can also be utilized for diagnosis and in the treatment of these tumors. Once diagnosed, management varies based on the type

of neoplasm. Metastatic tumors to the small bowel are rare, but direct invasion, and carcinomatosis tends to be the common presentation for nonprimary tumors. Operative treatment with extended resection is not possible with the small bowel like the extent of resection that can be performed in the colon. Now, treatment modalities and multidisciplinary approaches may offer improved survival.

EPIDEMIOLOGY

2 The American Cancer Society estimates that 6,900 new cases of small bowel cancer will be seen in 2015 with an estimated 1,100 deaths.⁴ The incidences increased from the 2008 query estimating 6,110 new cases of small bowel cancer and about the same number of deaths, approximately 1,110.⁵ These reports indicate a rising incidence of small bowel cancers, and are directly caused by the increasing incidence of carcinoid tumors of the small bowel.² This trend is occurring not only in the United States, but across the world. A recent review of cancer incidence showed a rising incidence of small bowel carcinoid tumors in England. The same rising incidence is demonstrated in the United States, along with a change in the distribution of the carcinoid tumors along the length of the small bowel.³

In the population below the age of 40, the incidence of small bowel neoplasms is low. The incidence for males and females is essentially the same. Sporadic, nonfamilial cancer occurs rarely in young patients.

PATHOGENESIS

With respect to the entire gastrointestinal tract, small bowel cancers are relatively rare. This raises the question as to why the region of the GI tract with the largest surface area has the lowest rate of cancer. Several factors have been identified as potential explanations; (1) the small bowel has liquid contents with an alkaline pH exposing the mucosa to a decrease in mechanical and chemical inflammation, (2) transit through the small bowel is rapid, thus shortening the time carcinogens are in contact with the mucosal surface, (3) there is a rapid turnover in epithelial cells in the mucosa outpacing the potential growth and development of neoplastic cells, (4) there is lower luminal bacterial load, particularly of anaerobes, which results in less total production of potential carcinogens, (5) the small bowel mucosa has an apparent enhanced ability to metabolize and/or detoxify certain dietary components or breakdown products that may be carcinogenic, and (6) the elaborate lymphoid tissue network surrounding the small bowel, and in particular, its ability to secrete immunoglobulin A, which might confer an increased immunologic-related tumor control.¹

3 The discrepancy between the number of small bowel adenocarcinomas and colorectal adenocarcinomas has pushed the research to a molecular level. There is substantial effort toward identifying the pathways for the mutation resulting in these cancers. These pathways include K-ras, E-cadherin, β -catenin, and p-53. The largest study of small bowel adenocarcinomas, $n = 21$, analyzed a variety of genes known to be involved with tumor mutagenesis in nonhereditary and nonperiapillary small bowel adenocarcinomas. The outcomes showed that all tumors presented with the hMLH1 and hMSH2 (usually absent in mismatch repair defective inherited tumors) genes in the tumor nuclei. No APC gene mutations were detected. One specimen had a replication error (RER). β -Catenin was expressed in 17 specimens, 8 specimens had decreased or no expression of E-cadherin, and 5 specimens had overexpression of p-53.⁶ This finding illustrates that the pathway to cancer that small bowel adenocarcinoma follows is different from the colorectal pathway.

PREDISPOSITION TO SMALL BOWEL CANCER

There are several predisposing risk factors for development of small bowel cancers. These include genetic and environmental factors.

Familial Adenomatous Polyposis

These patients have hundreds, and even thousands, of adenomas in their gastrointestinal tract, and have a 100% transformation rate to colorectal cancer if untreated. Interestingly, the leading cause of death for patients with familial adenomatous polyposis (FAP) is not the progression of colorectal cancer, due to the fact that most of the patients undergo a total colectomy. It is actually the malignant

transformation of the periampullary adenoma to adenocarcinoma.¹

Crohn Disease

Crohn disease is a significant risk factor to develop small bowel adenocarcinoma. The duration of disease, distal jejunal or ileal disease, early age of diagnosis, fistulizing-type disease, and male gender all contribute to a higher risk for development of small bowel adenocarcinoma.⁷ The relative risk was reported as 33 (95% CI: 15.9 to 60.9).⁸ The areas particularly susceptible are where longstanding inflammation has caused stricture formation. In these areas, the tumor tends to occur after at least 10 years of inflammation, and commonly contains signet-ring cell features similar to those found in colon cancer due to ulcerative colitis.

Celiac Disease

There is an increased risk for small bowel lymphomas as well as small bowel adenocarcinoma with those patients affected by celiac disease. Lymphomas tend to be both T-cell and non-Hodgkin lymphomas.⁹

Peutz–Jeghers Syndrome

This is an autosomal dominant syndrome characterized by hamartomatous polyps in the gastrointestinal tract and mucocutaneous melanin pigmentation. The increased risk of cancer is for breast, ovarian, testicular, pancreas, stomach, esophagus, and others. The mutation has been identified on the serine/threonine kinase 11 (STK 11) gene. Meta-analysis of Peutz–Jeghers syndrome indicated a relative risk for small bowel cancer of 520 when compared to the general population.¹⁰

Hereditary Nonpolyposis Colorectal Cancer

Hereditary nonpolyposis colorectal cancer (HNPCC) is an autosomal dominant gene that is associated with the mutation of mismatch repair genes. There is an increased risk to develop small bowel cancer with a relative risk of greater than 100 in carriers for the gene mutation.¹¹

Other Familial Syndromes

Multiple endocrine neoplasia type 1 (MEN-1), von Hippel–Lindau syndrome, and neurofibromatosis type 1 all carry increased risk for developing neuroendocrine, or carcinoid tumors.⁹

Dietary and Lifestyle Predisposition

There are several indicators to the increased risk of developing small bowel cancer including cigarette smoking, increased BMI/obesity, red meat consumption, and alcohol consumption.⁹

CLINICAL PRESENTATION

4 The majority of these tumors, whether benign or malignant, are typically asymptomatic and are encountered incidentally. The biggest factor relating to the way small bowel tumors present is the size and location within the small bowel. Generally, tumors less than 4 cm are asymptomatic. This is even truer with benign lesions. The most common presenting symptoms are weight loss (30% to 50%), nausea, vomiting, anemia, and abdominal pain.⁹ Late detection of asymptomatic malignant tumors results in metastases in about 50% of patients at the time of diagnosis.¹² Ulceration, perforation (in cases of lymphoma), obstruction, or bleeding are the most common presenting symptoms.¹³ Intussusception or volvulus can occur rarely. NETs can present as functional syndromes, such as “carcinoid syndrome” with flushing, diarrhea, and tachycardia with late valvular dysfunction due to fibrotic scarring induced by serotonin ([Table 51-1](#)).

DIAGNOSIS

Examining the small bowel with accuracy is a difficult process. Upper and lower gastrointestinal endoscopy provides little information because of the limited access to the vast amount of mucosal surface. Colonoscopic intubation of the ileocecal valve is ideal but is not possible in about 5% to 10% of the patients.¹⁴ Even with this intubation, only the most distal 25 cm of the terminal ileum can be

surveyed. During upper endoscopy (EGD) the duodenum is visualized in the proximal portion typically leaving the distal duodenum and the rest of the small bowel unevaluated. In certain cases, and with maximal effort, the endoscope can be advanced beyond the ligament of Treitz. However, the risk of duodenal injury increases due to pressure in the curve of the duodenum. Nevertheless, both of these procedures are indicated to begin the workup. The entire small bowel needs to be evaluated for a source of the symptoms. Newer modalities have been developed to facilitate evaluation of the small bowel.

Table 51-1 Complications Resulting From Small Bowel Tumors

Complication	Details
Weight loss	30–50% of patients History and physical examination of the patient
Nausea/vomiting	Nonspecific finding
Obstruction	Include in differential for patients never undergoing an abdominal surgery Diagnosis made with radiographs or CT scan
Ulceration/bleeding	Commonly with lymphoma Mass can be seen on CT scan, but ulceration and bleeding found with capsule endoscopy or deep endoscopy
Perforation	Emergent surgical management May see free air on radiographs or CT scan
Metastasis	50% metastasis with incidence of malignant small bowel tumors at time of diagnosis

CAPSULE ENDOSCOPY

CE is an ingestible miniature camera that is capable of producing images throughout the small bowel to depict its entire mucosal lining. CE was introduced first in 2000. CE is used most commonly to evaluate the small bowel for a source of occult gastrointestinal bleed (OGIB).

Generally, CE is safe and widely used as a diagnostic test.¹⁵ The only contraindications to its use are patients having swallowing disorders or bowel obstruction, with the possibility of capsule retention. There is a 2% capsule retention rate in most series.¹⁶ Other limitations to CE are that it is time consuming; there is no biopsy potential, and no therapeutic capability.

A large meta-analysis completed by Triester et al.¹⁷ demonstrated the incremental yield of CE over enteroscopy and small bowel barium radiography to be 35% and 59%, respectively. Although not statistically significant, the rate of identifying lesions was higher with CE. This is not surprising given CE’s ability to evaluate more mucosal surface area than other modalities. Lewis et al. performed a meta-analysis of CE compared to small bowel barium swallow, EGD, colonoscopy, and small bowel enteroscopy. Detection rate for CE was 87% and missed lesion rate was 10%. The combination of the other 4 modalities yielded a 13% detection rate and missed lesion rate of 73%. Both large meta-analyses demonstrate the CE capability and superiority.¹⁸

There are several capsules in use around the world. For example, the Given M2A imaging CE (Given Imaging; Yokneam, Israel) is a pill-shaped capsule measuring 11 mm × 26 mm. Within the capsule, the contents consist of a light source, an imaging chip, a battery source, and a radio transmitter with an internal antenna. Its visual field is 140 degrees and is magnified 8 times. This capsule travels through most of the small bowel with peristalsis and is excreted in the feces. The camera is able to take two images every second and transmits image to an external recording device. The capsule has a battery life lasting between 6 and 8 hours. At the completion of the study there are 50,000 images. There is software available to help the interpreter evaluate for a suspected bleeding source. There is no consensus on preprocedural bowel preparation, but some advocate for bowel prep. Prokinetics may be beneficial because there is a 20% incomplete small bowel transit.¹⁹

SMALL BOWEL ENTEROSCOPY

The difficulty to evaluate the small bowel is based on its location and length. The scope needed to

properly evaluate it is too long to have manual control of the tip. The bowel lies freely in the peritoneal cavity with essentially no fixation. Navigation with an endoscope has been traditionally difficult for this reason. Fixation points allow for proper evaluation of the foregut and colon in traditional endoscopy, but this is not the case for small bowel. DE utilizes a fixation point provided by the scope and the small bowel is brought to the viewing tip of the scope. Traditional endoscopy utilizes pushing the endoscope through the gastrointestinal tract which is impossible without external intraoperative manipulation of the bowel over the scope. Using this new method for evaluation has provided endoscopists with a steep learning curve and added length of time to complete the evaluation.

5 The disadvantages of CE are difficulty with orientation, inability to biopsy, possible obstruction, and capsule retention. Small bowel enteroscopy, DAE, or DE, are excellent alternative modalities.

DE allows the operator to obtain biopsies and to perform therapeutic interventions. There are three methods for DE available today.

Double-Balloon Enteroscopy

This technique was developed in 2001 by Hironi Yamamoto,²⁰ and introduced into Korea in 2004 where it found its way to the United States. This endoscope consists of a balloon at the tip of an endoscope that has a length of 140 cm. An overtube, also containing a balloon at the tip, fits over the scope to employ a push-and-pull technique.²¹ This allows for examination of 240 to 360 cm. While the overtube balloon is inflated, the scope is advanced with its balloon deflated. The inflated overtube balloon will allow for a fixation point for the scope to maneuver through the small bowel. Once a significant advancement has occurred, the endoscope balloon is inflated, and the overtube balloon deflated. The overtube then slides along the endoscope to the end of the scope. The overtube balloon is reinflated to provide another fixation point as the endoscope balloon is taken down and advanced once more. This outlines the push technique as the endoscope is advanced with the overtube balloon inflated. The pull technique is when both balloons are inflated and the endoscopist pulls back on both. This will reset the ability to start the push technique again. This progression continues until the entire small bowel is evaluated.

The two most common enteroscope systems used have scope diameters of 8.5 mm and 9.3 mm with working channels of 2.2 mm and 2.8 mm. The working channels allow for the therapeutic and diagnostic options provided by these systems.

Double-balloon enteroscopy (DBE) is the most studied method to date and shows a diagnostic yield of 60% to 80% in patients with occult GI bleeding and other small bowel pathologies.²² However, it may not be feasible in all patients and success rates vary from 16% to 86%.^{20,23} This variation is due to differing patient populations across the world and the specific disease processes.

The main limitations to DBE are the invasive nature and prolonged duration of the procedure. The complication rate overall is reported as 0.8% but can be higher while performing therapeutic procedures such as electrocautery for a GI bleed, polypectomy, or dilation. The main complications are pancreatitis, ileus, and perforation.²⁴⁻²⁶

Single-Balloon Enteroscopy

This system was developed in 2007 and is similar to DBE, but the distinguishing trait is that this system lacks the endoscope balloon. There is still a balloon on the overtube used over the scope. Substituting in the endoscope balloon's place, the scope tip is hooked to hold the scope fixed to aid in the advancement of the overtube. Overall, the concept is the same as to fix a portion of the small bowel to allow for advancement of the endoscope.

The overtube is referred to as the splinting tube which has a hydrophilic coating that is activated with application of 30 mL of water. Radiopaque material is present at the tip to aid in the advancement with fluoroscopy.

Spiral Enteroscopy

Also in 2007, spiral enteroscopy (SE) was introduced which provides potential benefits with regard to shorter procedure time. A raised spiral on the exterior of the scope pulls the small bowel over the scope as it advances. This scope is 118 cm in length and has a diameter of 9.8 mm. The raised spiral grooves are 16 mm high. Clockwise rotation of the scope will advance the scope and counterclockwise rotation will withdraw the scope.

Studies for SE demonstrate shorter insertion depths with faster procedure times. There is variation in the insertion depth varying from 176 cm to 262 cm.^{27,28} The complication rate is noted to be 0.3% with

a perforation rate of 0.27%.²² Overall, the device is simple to use with a learning curve of 5 cases.^{22,29}

Exploratory Laparoscopy

The role of laparoscopy has improved the management of small bowel lesions over the last decades.^{30,31} The advantages of DAE and imaging have been discussed at length, but the role for laparoscopic assessment of the peritoneal cavity for small bowel tumors plays a significant role in both diagnosis and treatment. Furthermore, the improvements in laparoscopy and surgeons abilities with a laparoscope have enabled minimally invasive management of small bowel tumors. Johnson et al.³² evaluated all small bowel obstructions in a single institution requiring surgery. Successful completion of a laparoscopic approach was possible in 32% of patients (conversion to an open procedure was necessary in 40% of patients, with 20% of the conversions secondary to tumor. Small bowel was resected in 8% of the laparoscopic cases, 64% of the converted cases, and 41% of the case done completely open. Length of stay of patients with a purely laparoscopic approach was 7.7 days versus 11 days in the converted cases and 11.4 in the purely open cases.

There are distinct advantages to laparoscopy when the ability of the surgeon allows this approach. Direct visualization of the small bowel on the extraluminal side adds significant value to the management of small bowel tumors. Complete evaluation of the small bowel can be obtained laparoscopically by examining the entire small bowel in a systematic approach in order to visualize all aspects of the small bowel including the mesentery. In conjunction with endoluminal approaches, like small bowel enteroscopy, lesions can be located, biopsied, and if needed, resected.

The laparoscopic approach is limited by the extent of the disease process being investigated. Local spread of small bowel tumors will likely affect directly adjacent small bowel or other nearby organs. This invasion can make it impractical to proceed laparoscopically if one is to provide the patient with the best outcome. Also, most common tumors of the small bowel affect the mucosal surface only and extraluminal visual examination may be inadequate to identify the lesion. Exceptions to this would be utilizing small bowel enteroscopy to tattoo the lesion which can be easily seen from the extraluminal side. This would also facilitate a sound oncologic resection of the tumor. Hand-assisted laparoscopy is also helpful if palpation is essential and a small incision is desired.

A laparoscopic case should be converted to an open technique if conditions prevent oncologically sound technique in order to provide the patient with the best outcome.

MANAGEMENT

Benign

Adenomas are benign lesions that have malignant potential. This tends to follow the malignant degeneration seen in polyps of the large bowel, described in 1990,³³ and most commonly seen with periampullary tumors.³⁴ Interestingly, the distribution of adenomas tends to follow the small bowel's exposure to bile, making the most common location immediately distal to the papilla in the second portion of the duodenum and progressively decreases in the more distal intestine.³⁵

Hamartomas are benign vascular tumors with a low malignant potential and usually associated with Peutz-Jeghers syndrome.¹³ Lipomas are encountered as a single mass or as multiple and are usually encountered incidentally. Hemangiomas are rare benign tumors in the small bowel that present as GI bleeding.

The only reason for operative management of a benign small bowel lesion is to control symptoms. Mass effect causing intussusception or obstruction, hemorrhage, or a questioned presence of malignancy generates the need for local resection of the lesion. The diagnostic dilemma is the most common reason for resection of an incidentally found mass on contrast study or endoscopy. Hemangiomatic lesions can be resected or managed with angiographic embolization. The use of angiographic isolation and intraoperative angiographic methylene blue injection can be very helpful to guide resection of a bleeding field of small bowel angiomas.

Malignant

Discovery of small tumors is rare. Within the group of malignant tumors found in the small bowel, there are four main types. The most recent data from a single-institution tumor registry show that carcinoid tumors of the small bowel have surpassed the incidence for adenocarcinomas of the small bowel.¹ A total of 1,260 tumors were examined and their distribution throughout the small bowel was discussed.

Carcinoid tumors (33%), adenocarcinomas (30%), lymphoma (16%), GIST (7%), and other cell types found (13%). The authors separated the different tumor types based on location within the small bowel, which changed the order of the most common tumors seen in each portion.

Neuroendocrine Tumors

NETs of the small bowel have increased in incidence significantly over the last 40 years, and mirror the overall increase in gastrointestinal NETs throughout the entire gastrointestinal tract. This is reflected in the recent SEER data ranking gastrointestinal NETs second, only behind colorectal cancer, as the most common cancer of the GI tract.³⁶ This has also been shown in Sweden³⁷ and in England.³ NETs arise from a diffuse neuroendocrine system made up of secretory cells, called enterochromaffin cells, causing the propensity for these tumors to produce vasoactive substances. NETs, formerly known as carcinoid tumors, can be almost benign or very aggressive. Carcinoid syndrome was characterized in 1954 by Thorson et al. who associated the presence of the metastatic carcinoid tumor with the presence of some abnormal symptoms.³⁸ They related the increased production of serotonin causing systemic effects such as diarrhea, flushing, bronchospasm, cutaneous vasomotor symptoms, and cardiovascular dysfunction. Serotonin was actually extracted 1 year earlier from carcinoid tumors and labeled as the active ingredient in the symptoms.^{39,40} Serotonin is derived from its precursor tryptophan, and when in circulation, it elicits particular symptoms. The liver will inactivate serotonin to make 5-hydroxyindoleacetic acid (5-HIAA) which is excreted by the kidney.⁴¹

Table 51-2 Pathologic Classification of Neuroendocrine Tumors

Pathologic Classification of Neuroendocrine Tumors		
Differentiation	Grade	Criteria
Well differentiated	Low (typical)	<2 mitoses/10 HPF and ≤2% Ki67 index
Intermediate (atypical)	2–20 mitoses/10 HPF or 3–20% Ki67 index	
Poorly differentiated	High	>20 mitoses/10 HPF or >20% Ki67 index

From Strosberg J. Neuroendocrine tumours of the small intestine. *Best Pract Res Clin Gastroenterol* 2012;26(6):755–773.

The presentation of NETs comes from two basic components of the tumor. First, the tumor sizes can elicit effects such as obstructive symptoms or abdominal pain. Second, the hormonal secretion of the tumors can lead to symptoms, such as carcinoid syndrome. About 50% of NETs present in the ileum¹ and the majority of those are in the distal 60 cm of the ileum.⁴¹ Most commonly these tumors metastasize to the liver, mesentery, and peritoneum.⁴² The intraluminal effects of these tumors usually leads to the obstructive symptoms and the desmoplastic reaction of the small bowel mesentery produces the abdominal pain associated with the tumor burden.

6 Metastasis of small bowel NETs is related to primary tumor size. A literature review of 185 patients with small bowel NET showed an 85% nodal metastasis and 47% distant metastasis with tumors greater than 2 cm. With tumors between 1 and 1.9 cm, 70% had nodal metastasis and 19% had distant metastasis. With tumors less than 1 cm, there was 12% nodal metastasis and 5% distant metastasis.⁴³ Even though small NETs can metastasize, the risk of metastases does correlate with size of the primary tumor. This is influenced by the early invasion of bowel wall lymphatics and blockage of the lymphatics in the mesentery, forcing cells to flow retrograde into lymphatics along the bowel.

The mitotic rate and Ki-67 index are measured in order to provide the histologic grade of these tumors, which correlates closely with clinical behavior. These measurements categorize the tumors into one of three categories by grade; low, intermediate, and high. The 5-year survival rates are 79%, 74%, and 40%, respectively. Low and intermediate grade typically fall into the well-differentiated category and high grade is considered poorly differentiated (Table 51-2). Resection to maximally debulk the tumor, or maximize cytoreduction, is the only chance for cure in NETs.

A formal TNM staging classification has recently been instituted. This stratifies tumors into localized, locally advanced, and metastatic categories with associated 5-year survivals of 95%, 84%, and 51%, respectively (Table 51-3). Shortly after, in 2007, the American Joint Committee on Cancer adopted a TNM staging system proposed by the European Neuroendocrine Tumor Society (ENETS) specifically for tumors of the lower jejunum and ileum. This factored out the poorer prognosis of the tumors in other parts of the body such as the colon, rectum, and appendix⁴⁴ (Tables 51-4 and 51-5). Five-year survival

rates were much different showing 100% for stage I and stage II cancers, 91% for stage III cancers, and 72% for stage IV cancers. Survival rates were slightly improved with presentation of another 270 NETs by Jann et al.⁴⁵

7 Generally, diagnosis is made based on radiographic findings in conjunction with tumor markers. There are three common radiographic modalities used to diagnose these tumors, which include CT scan and MRI enterography and octreotide scanning.

Abdominal CT can help locate the primary tumor, but three-phase CT should be used for optimal evaluation of liver metastasis. The clinician should be mindful of the affinity of NETs to metastasize to the liver, especially in the setting of physical findings consistent with neuroendocrine peptide secretion. The arterial phase and the portal venous phase are typically the phases that maximize the ability to locate the metastatic lesions because NETs are typically rich in vascularity.⁴⁶ For the same reason, MRI can also be used to locate and evaluate metastatic lesions to the liver.

Table 51-3 5-Year Survival Rates by Carcinoid Location (1973–1997)^a

Site	All Stages	Local Stage	Regional Stage	Distant Stage
Stomach	75.1%/55.3%	90.2%/69.6%	40.4%/27.2%	18.0%/9.0%
Small bowel	76.1%/54.6%	94.5%/70.4%	84.4%/64.1%	51.2%/32.4%
Appendix	76.3%/65.0%	95.6%/87.8%	80.0%/67.6%	37.5%/26.8%
Colon	69.5%/41.8%	94.1%/77.1%	72.5%/35.3%	27.8%/4.1%
Rectum	87.5%/77.8%	94.9%/86.2%	53.7%/42.1%	14.6%/13.1%

^aCancer-specific survival/relative overall survival.
Survival rates are all age-adjusted to standard 2000 population.

Table 51-4 Proposal for a TNM Classification for Endocrine Tumors of Lower Jejunum and Ileum

T-primary tumor	
TX	Primary tumor cannot be assessed
T0	No evidence of primary tumor
T1	Tumor invades mucosa or submucosa and size <1 cm
T2	Tumor invades muscularis propria or size >1 cm
T3	Tumor invades subserosa
T4	Tumor invades peritoneum/other organs
For any T, add (m) for multiple tumors	
N regional lymph nodes	
NX	Regional lymph nodes cannot be assessed
N0	No regional lymph node metastasis
N1	Regional lymph node metastasis
M	Distant metastasis
MX	Distant metastasis cannot be assessed
M0	No distant metastases
M1	Distant metastasis

Rindi G, Klöppel G, Couvelard A, et al. TNM staging of midgut and hindgut (neuro) endocrine tumors: a consensus proposal including a grading system. *Virchows Arch* 2007;451(4):757–762.

NETs often express somatostatin receptors rendering them detectable by imaging with radiolabeled forms of somatostatin called octreotide.⁴⁷ This was discovered during the refinement of the octreoscan, or SRS (somatostatin receptor scintigraphy). Five subtypes of somatostatin receptors have been identified and the somatostatin analogs from the octreotide scan bind with subtypes 2 and 5 which are present in 70% to 90% of NETs.⁴⁸ With the progression of diagnostic ability came the use of single-photon emission computed tomography (SPECT) to enhance the accuracy of differentiating areas of pathologic and physiologic uptake in the abdomen. This is a full-body scan that enables visualization of somatostatin uptake throughout the entire body.

Further use of radiolabeled markers has brought about advances in positron emission tomography with use of functional radiotracers for imaging. The advantages to this platform are the higher spatial resolution than the octreotide scanning. This also offers advantages for detecting smaller lesions than other scanning methods. Octreotide, MBIG, and PIET scanning are used for follow-up of patients and staging of patients for distant disease when planning aggressive, multiorgan resections.

Making the diagnosis of small bowel NET is often late in its course and the chances of metastatic lesions being present are high because of this. However, surgical management is still an option for patients in cases of localized tumor burden and distant metastasis. Survival outcomes are better for those patients with stage I and stage II diseases, as previously discussed, and surgical excision of the primary tumor and local node metastasis is still the only curative therapy for these patients.⁴⁹ The primary focus in any instance with the presence of NET is to control the functional disorder associated with the tumor present, such as carcinoid syndrome. Several options are applicable to the tumor itself once any functional disorder is controlled and treated. These include close surveillance of indolent tumors, radiofrequency ablation (RFA) therapy for liver metastases, systemic therapy with somatostatin analogs or interferon, or cytotoxic or molecular targeted therapies. These are all options that can be used and have never been compared in a controlled comparison, making these therapies highly individualized.

Table 51-5 Disease Staging for Endocrine Tumors of Lower Jejunum and Ileum

Stage			
Disease Stages	T-Primary Tumor	N-Regional Nodes	M-Distant Metastasis
Stage I	T1	N0	M0
Stage IIA	T2	N0	M0
Stage IIB	T3	N0	M0
Stage IIIA	T4	N0	M0
Stage IIIB	Any T	N1	M0
Stage IV	Any T	Any N	M1

8 Chromogranins are glycoproteins that are stored in secretory vesicles within neuroendocrine tissue.⁴¹ There are three distinct types named chromogranin A, B, and C. Chromogranin A tends to be the most sensitive indicator of a NET with varied sensitivity and specificity. For instance, false positives are noted in patients with atrophic gastritis, renal insufficiency, inflammatory bowel disease, and patients taking proton pump inhibitors.^{50,51} Since chromogranin A has a low specificity, it is not used as a screening tumor marker for NETs, but can be used in those patients with an established diagnosis to assess disease progression and response to therapy in surgical resection.⁴¹

Surgical management with resection and the use of RFA still provides the best survival benefit for all patients with localized and advanced NET.^{52,53} However, if needed, debulking procedures have been shown to be effective in improving symptoms⁵² with greater than 90% resection. Planning for a two-step approach for radical resection to achieve complete resection has been shown to be effective.⁵⁴ With high tumor grades, recurrence rates can be as high as 81%.⁵⁵ Transarterial chemoembolization (TACE) has been shown to be highly effective against nonresectable diffuse liver lesions to reduce symptoms.⁵³

Medical management of NET includes a wide variety of agents including somatostatin analogs (octreotide) and peptide receptor radionucleotide therapy (PRRT), chemotherapeutic agents (doxorubicin–streptozotocin, dacarbazine, temozolomide, oxaliplatin, or interferon), monoclonal antibody therapy (bevacizumab), mTOR inhibitors (temsirolimus and everolimus), and multikinase inhibitors (sunitinib, sorafenib, and pazopanib).

A combination of both medical and surgical management is outlined in [Algorithm 51-1](#).

Since carcinoid can develop in all areas of the intestine, surveillance with endoscopy is important. Scanning with CT/MRI of the liver can guide reexploration and resection. Octreotide scanning, MBIG, or PET scanning can be helpful in controversial cases of possible metastases.

Small Bowel Adenocarcinoma

Small bowel adenocarcinomas represent the second-most common cancer of the small bowel with an incidence of 7.3 cases per million worldwide.^{2,56,57} Small bowel adenocarcinoma, along with colorectal cancer, is more common in developed countries, and has higher incidence rates in North America and Western Europe.⁵⁸ Adenocarcinoma can be found throughout the entire small bowel, 56% is found in the duodenum.² Goodman et al. performed an examination of 26 population-based cancer registries to find that the overall age-adjusted incidence rates for small bowel adenocarcinoma favored men over women (7.7 to 5.1), and both men and women exhibited the same trend with regard to race. Black populations had an age-adjusted incidence rate of about twice the rate of white individuals, and the Hispanic population followed. The lowest incidence is in the Asian/Pacific Islander population.⁵⁹

Algorithm 51-1

Algorithm 51-1. Management algorithm for patients with advanced neuroendocrine tumors (NETs) of the gastrointestinal tract. mTOR, mammalian target of rapamycin; PPI, proton pump inhibitor; RFA, radiofrequency ablation; TAE, transarterial embolization. (Walter T, Brixi-Benmansour H, Lombard-Bohas C, et al. New treatment strategies in advanced neuroendocrine tumours. *Dig Liver Dis* 2012;44(2):95–105.)

Presentation for small bowel adenocarcinoma is very nonspecific with the most common symptom on presentation being abdominal pain (45% to 76%).⁵⁷ Other common symptoms include nausea and vomiting, weight loss, fatigue and anemia, and GI bleeding.^{60,61} Interestingly, with the indolent presentation of these cancers, patients can recall symptoms for long periods of time prior to diagnosis. Talamonti et al.⁶¹ were able to identify a mean duration of symptoms at presentation at 10 months.

Simple laboratory testing can identify abnormalities that can indicate bleeding, and there are no specific tumor markers associated with a diagnosis of small bowel adenocarcinoma. Carcinoembryonic antigen (CEA) and carbohydrate antigen 19-9 (CA 19-9) are elevated in only about 30% to 40% of patients.⁶² Radiologic and endoscopic modalities provide the best method for detecting small bowel adenocarcinoma. Unfortunately, these modalities can fail to make a diagnosis given the nonspecific nature of the presenting symptoms.

Evaluation of the small bowel in order to make a diagnosis of small bowel adenocarcinoma can include upper GI swallow study with small bowel follow-through or enteroclysis. The major disadvantage to these modalities is the inability to assess extraluminal spread given the often late presentation. The use of CT and MR with enterography has drastically improved the ability to detect these cancers. The sensitivity rate for detecting small bowel tumors was 84.7% and a specificity of 96.9% when using CT enterography.⁶³ Using MR enterography (MRE) for detecting small bowel tumors has a sensitivity of 91% and a specificity of 95%.⁶⁴

Endoscopic evaluation has been discussed elsewhere in this chapter, but EDG plays an important role in detecting small bowel adenocarcinomas because of the high rate of incidence in the duodenum.

The prognosis of small bowel adenocarcinoma varies. Prognosis is directly related to the tumor staging as it is the single most important prognostic indicator.⁶⁰ There are several factors that are related to the poor prognosis aside from advanced staging, including poor differentiation, positive margins after resection, duodenal location, male gender, elderly age, and black ethnicity.⁵⁷ Optimal diagnostic lymph node harvest at the time of surgery has been identified as requiring either 8 or 10 or more nodes for accurate assessment.^{65,66} Patients can be staged (Table 51-6) and their disease-specific survival rates can be assessed based on the tumor site (Fig. 51-1) and change based on the number of

lymph nodes examined (Fig. 51-2) and the number of positive lymph nodes (Fig. 51-3).

Table 51-6 Disease-Specific Survival According to Disease Stage, Total Number of Lymph Nodes Assessed, and Total Number of Positive Lymph Nodes

No. of Lymph Nodes	% Cumulative 5-Year DSS		
	Stage I	Stage II	Stage III
TLN			
0	70	44	
1–7	93	69	43
>7	95	83	56
PLN			
<3			58
>3			37
LNR ^a			
T1 (0.02–0.2)			63
T2 (0.21–0.5)			53
T3 (0.52–1)			30

^aStratified by tertiles.
DSS, disease-specific survival; TLN, total number of lymph nodes assessed; PLN, total number of positive lymph nodes; LNR, lymph node ratio.
Overman MJ, Hu CY, Wolff RA, et al. Prognostic value of lymph node evaluation in small bowel adenocarcinoma: Analysis of the surveillance, epidemiology, and end results database. *Cancer* 2010;116(23):5374–5382.

Surgical management is the mainstay of therapy for small bowel adenocarcinoma with locoregional disease.⁵⁷ It has been known for almost 2 decades that resection of duodenal adenocarcinomas yields a 56% survival at 5 years with complete surgical resection and 0% survival at 5 years without resection.⁶⁷ Duodenal adenocarcinomas can be managed with pancreaticoduodenectomy or with segmental resection for the distal third and fourth portions for resectable tumors. Nodal involvement should prompt adjuvant therapy, but otherwise observation is sufficient (Algorithm 51-2). Jejunal and ileal adenocarcinomas should be managed with similar principles of segmental resection and regional lymph node dissection, with a right hemicolectomy for tumors involving the distal ileum.⁵⁷

Medical management of small bowel adenocarcinoma consists of adjuvant therapy which is aimed toward controlling recurrence of adenocarcinoma at distant sites. Distant recurrence predominates over the high locoregional recurrence for duodenal adenocarcinomas.⁵⁷ Poultides et al. recently showed in a series of 122 patients who had a pancreaticoduodenectomy for duodenal adenocarcinoma, the first site of recurrence was distant 59% of the time, locoregional 19% of the time, and both in 22% of the cases.⁶⁸ Adjuvant therapies involve 5-fluorouracil/capecitabine, FOLFOX/CAPOX, FOLFIRI, or gemcitabine.

Lymphoma

There is an abundant amount of lymphoid tissue in the small bowel, especially in the terminal ileum. Lymphomas account for about 15% to 20% of small intestine neoplasms.¹² This mirrors the malignant transformation distribution patterns throughout the small intestine with regard to lymphoma. SEER database analysis from 1975 to 2003 shows a distribution of 60% to 65% in the ileum, followed by 20% to 25% in the jejunum, and 6% to 8% in the duodenum.⁶⁹ However, secondary lymphoma is much more common than primary lymphoma because the gastrointestinal tract is the most common site for extranodal disease.¹³

Figure 51-1. These Kaplan–Meier curves illustrate disease-specific survival stratified by (A) disease stage, (B) subsite in the small bowel for stage I and II diseases, and (C) subsite in the small bowel for stage III disease. Codes for the duodenum (C17.0), jejunum, (C17.1), and ileum (C17.2) are from the International Classification of Diseases for Oncology and Related Health Problems 10th Revision. (Overman MJ, Hu CY, Wolff RA, et al. Prognostic value of lymph node evaluation in small bowel adenocarcinoma: Analysis of the surveillance, epidemiology, and end results database. *Cancer* 2010;116(23):5374–5382.)

The typical clinical presentation of small bowel lymphoma is nausea, vomiting, abdominal pain, and weight loss. Severe symptoms, such as obstruction, intussusceptions, or perforation are rare.¹²

Figure 51-2. These Kaplan–Meier curves illustrate disease-specific survival stratified by (A) the total number of lymph nodes assessed (TLN) in patients with stage I and II diseases and (B) the TLNs assessed in patients with stage III disease. (Overman MJ, Hu CY, Wolff RA, et al. Prognostic value of lymph node evaluation in small bowel adenocarcinoma: Analysis of the surveillance, epidemiology, and end results database. *Cancer* 2010;116(23):5374–5382.)

Several types of lymphoma can occur in the small bowel. However, the most commonly encountered lymphoma is diffuse large B-cell lymphoma. Despite the incidence of lymphoma in the small intestine, surgery is typically not the method for management. These patients should undergo resection in situations of obstruction or bleeding, and should still receive chemotherapy.¹² Immunoproliferative small intestinal disease occurs in patients who are chronically immunosuppressed as a result of infection by *Helicobacter pylori* and *Campylobacter jejuni*. Antibiotic therapy for these bacteria usually results in regression of immunoproliferative small intestinal disease. Most of these patients relapse and will need radiation and chemotherapy with nutritional support.^{70,71}

Gastrointestinal Stromal Tumor

9 GISTs are the most mesenchymal tumors of the small bowel. GISTs are found in the stomach (60% to 70%), small intestine (20% to 30%), and in the duodenum (4% to 5%).⁷² GISTs are known to arise from the interstitial cells of Cajal, which are described as the gastrointestinal pacemakers.⁷³ Coincidentally, that same year GISTs were termed gastrointestinal pacemaker cell tumors, Hirota et al.⁷⁴ recognized the c-kit proto-oncogene which codes for a tyrosine kinase inhibitor, as the genetic mutation leading to GISTs. As a result, there has been a dramatic shift in the way GISTs are managed.

Figure 51-3. These Kaplan–Meier curves illustrate disease-specific survival stratified by (A) the number of positive lymph nodes (PLN) and (B) the lymph node ratio (LNR) in tertiles. (Overman MJ, Hu CY, Wolff RA, et al. Prognostic value of lymph node evaluation in small bowel adenocarcinoma: Analysis of the surveillance, epidemiology, and end results database. *Cancer* 2010;116(23):5374–5382.)

The diagnosis of small bowel GISTs is similar to that of other small bowel tumors; however, the GIST is unique with regard to the submucosal origin and its likelihood to grow in size away from the lumen of the small bowel. This also makes it difficult to make a diagnosis with intraluminal biopsy. A study by Bümming et al. in 2006 demonstrated that only one-third of diagnoses are made with biopsies, and that the most common method of detection was endoscopy and CT scan.⁷⁵ Most commonly, patients with GISTs present with vague abdominal symptoms, pain, GI bleeding from a mucosal erosion, or an abdominal mass.⁷⁶

GISTs do not have the malignant pattern predicted in other types of cancers based on histopathology alone. Several factors influence malignant behavior including tumor size, mitotic rate, tumor location, kinase mutational status, and occurrence of tumor rupture. Mitotic rate and tumor size are the most commonly acceptable indices for prognosis.⁷²

Tumor size and location dictate the type of treatment. Complete surgical resection remains the only method for curative treatment, and simple negative margins are needed, as wide margins have not shown significant benefit.⁷² Small segmental resection of the small bowel is adequate because GISTs rarely metastasize to lymph nodes. Lymph node dissection is not warranted. En bloc resection should be done for locally advanced GISTs.⁷² Overall 5-year survival rate for patients with complete resection of GISTs is 50% to 65%.^{72,76–78}

Algorithm 51-2. Algorithm showing the management of patients with small bowel adenocarcinomas. The treatment strategy depends on disease stage and involves en bloc resection for locoregional disease and systemic chemotherapy for metastatic disease. All current recommendations are based on case series, retrospective reviews or nonrandomized prospective trials because of an absence of any randomized data. 5-FU, 5-fluorouracil; CAPOX, capecitabine and oxaliplatin; FOLFIRI, 5-FU, leucovorin and irinotecan; FOLFOX, 5-FU, leucovorin and oxaliplatin; KRAS-WT, KRAS wild-type; PS, performance status; XRT, radiation therapy. (Elias D, Lefevre JH, Duvillard P, et al. Hepatic metastases from neuroendocrine tumors with a “thin slice” pathological examination: they are many more than you think. *Ann Surg* 2010;251(2):307–310.)

Patients have a defined risk for recurrence and may benefit from adjuvant therapy. The Modified NIH–Fletcher GIST Risk Assessment Criteria is presented in [Table 51-7](#). Other risk assessment tools are available such as Armed Forces Institute of Pathology Classification and the Memorial Sloan-Kettering Cancer Center Prognostic Nomogram. Adjuvant therapy utilizes imatinib (Gleevec). This drug is used in the treatment algorithms for patients with advanced or metastatic GIST or with resectable GIST. [Algorithm 51-3A](#) shows these algorithms. Imatinib is a competitive inhibitor for multiple tyrosine kinase inhibitors and was originally recommended for chronic myelogenous leukemia treatment. It became first-line treatment for GIST once it was recognized to disrupt the KIT oncogene in GISTs.⁷⁹ Shortly after that, imatinib was approved for use in unresectable or metastatic disease shown in [Algorithm 51-3B](#).^{80,81} A randomized prospective study was done in 2009 to evaluate imatinib for the use in adjuvant therapy, showing significant improvement in 5-year recurrence-free survival, 98% versus 83%, respectively, in the treatment group over placebo.⁸² The NCCN guidelines in the management of GISTs provide a standard algorithm.⁸³

Table 51-7 Modified NIH–Fletcher GIST Risk Assessment Criteria

Risk Category	Tumor Size (cm)	Mitotic Index (/50 HPF)	Primary Tumor Site
Very low risk	<2.0	≤5	Any
Low risk	2.1–5.0	≤5	Any
Intermediate risk	2.1–5.0	>5	Gastric
	<5.0	6–10	Any
	5.1–10.0	≤5	Gastric
High risk	Any	Any	Tumor rupture
	>10	Any	Any
	Any	>1G	Any
	>5.0	>5	Any
	2.1–5.0	>5	Nongastric
	5.1–10.0	≤5	Nongastric

Algorithm 51-3. Treatment algorithms for patients with (A) advanced/metastatic GIST and (B) resectable GIST. GIST indicates gastrointestinal stromal tumor. (Mullady DK, Tan BR. A multidisciplinary approach to the diagnosis and treatment of gastrointestinal stromal tumor. *J Clin Gastroenterol* 2013;47(7):578–585.)

METASTATIC TUMORS TO THE SMALL BOWEL

10 Metastasis to the small bowel occurs in two different ways, either from distant spread or direct invasion from a nearby organ malignancy. The most common are from breast cancer and melanoma. Melanoma is the most common extraintestinal malignancy with predilection to metastasize to the small bowel (Fig. 51-4).⁸⁴ Patients with metastatic melanoma to the small bowel often present with other extraintestinal metastasis.⁸⁵ Primary tumors of intraperitoneal organs such as colon, ovary, uterus, and stomach metastasize to the small bowel.⁸⁴

Figure 51-4. Metastatic melanoma to small bowel resecting en bloc.

Patients with small bowel metastasis are usually offered palliative systemic chemotherapy. Other palliative measures can be considered on a case-by-case basis including surgical resection, internal bypass, or usage of an endoscopically placed stent.⁹

SECTION G: PANCREAS

Chapter 52

Pancreas Anatomy and Physiology

Taylor S. Riall

Key Points

- 1 The pancreas is both an endocrine and exocrine organ.
 - 2 The primary function of the exocrine pancreas is to synthesize and secrete enzymes necessary for digestion.
 - 3 The primary function of the endocrine pancreas is regulation of body energy, primarily through control of carbohydrate metabolism. Pancreatic endocrine hormones also play a critical role in the complex regulation of pancreatic secretion and digestion.
 - 4 Congenital anomalies of the pancreas largely result from failure of rotation or fusion of the ventral and dorsal pancreatic buds.
 - 5 The pancreatic islets of Langerhans are composed of four major cell types – alpha (A), beta (B), delta (D), and pancreatic polypeptide (PP or F) cells which primarily secrete glucagon, insulin, somatostatin, and PP, respectively.
 - 6 The different types of islet cells are not evenly distributed throughout the pancreas leading to a differential distribution of functional neuroendocrine tumors. In addition, resection of different parts of the pancreas has differing endocrine effects.
 - 7 Pancreatic endocrine secretion also regulates pancreatic exocrine secretion. Insulin stimulates pancreatic exocrine secretion, amino acid transport, and synthesis of protein and enzymes, whereas glucagon acts in a counter-regulatory fashion, inhibiting the same processes.
 - 8 Tests of pancreatic exocrine function include the secretin test, 24-hour fecal fat determination, dimethadione (DMO) test, the Lundh test meal, the triolein breath test, and the paraaminobenzoic acid (PABA) test. These tests help differentiate steatorrhea due to pancreatic insufficiency from other digestive disorders.
 - 9 Exogenous administration of somatostatin inhibits the release of insulin, glucagon, growth hormone, and pancreatic polypeptide.
 - 10 Knowledge of the relationship of the pancreas to surrounding structures including the stomach, duodenum, distal bile duct, hepatic arterial blood supply, splenic artery and vein, celiac axis, superior mesenteric artery and vein, portal vein, spleen, adrenal glands, colon and kidneys is critical in preventing injury to these structures during pancreatic surgery.
 - 11 Resectability in pancreatic cancer in the absence of metastatic disease depends on the extent of involvement of the tumor with the major vascular structures including the superior mesenteric artery, superior mesenteric vein (SMV), portal vein, and celiac axis.
-

INTRODUCTION

1 The pancreas is a digestive organ with both exocrine and endocrine function. The exocrine pancreas constitutes 80% of the pancreatic mass and comprises acinar and ductal cells.

2 Acinar cells synthesize and secrete over 20 enzymes into the complex pancreatic ductal network, which then delivers them to the duodenum. The pancreatic secretions are alkaline and provide the optimal environment for the enzymes to carry out their digestive function in the small intestine.

3 The pancreatic endocrine cells are organized in discrete groups throughout the pancreas, called islets of Langerhans. The islets directly secrete hormones including insulin, glucagon, and somatostatin, directly into the blood stream in endocrine fashion. The primary function of the endocrine pancreas is regulation of body energy, primarily through control of carbohydrate metabolism. Pancreatic endocrine hormones also play a critical role in the complex regulation of pancreatic secretion and digestion.

The pancreas lies transversely in the retroperitoneum at the level of the second lumbar vertebrae. Understanding of the embryology of the pancreas is critical for recognizing rare congenital anomalies, understanding their significance, and treating them appropriately. In addition, when performing pancreatic and other upper abdominal operations, it is critical to understand the close relationship of the pancreas to adjacent organs (duodenum, stomach, spleen, transverse colon, bile duct, and left adrenal gland) and major vessels (celiac axis, superior mesenteric artery, superior mesenteric vein (SMV), splenic artery and vein, portal vein, inferior mesenteric vein, and vena cava). Knowledge of the normal pancreatic exocrine and endocrine physiology provides insight into the pathologic processes and subsequent treatments that can affect the normal function of the pancreas.

EMBRYOLOGY

Normal Pancreatic Embryology

The pancreas begins developing during the fifth week of gestation. Pancreatic development begins at the junction of the foregut and midgut as two endodermal pancreatic buds, the dorsal bud and the ventral bud. The dorsal and ventral buds comprise endoderm covered in splanchnic mesoderm. Both the acinar and islet cells differentiate from the endodermal cells found in the embryonic buds while the splanchnic mesoderm eventually develops into the dorsal and ventral mesentery.

The dorsal bud forms first and is larger. It ultimately forms much of the head, body, and tail of the pancreas. As the duodenum grows and rotates, the ventral bud rotates clockwise ([Fig. 52-1](#)) and fuses with the dorsal bud forming the uncinate process and inferior head of the pancreas. In the majority of cases, the duct in the ventral bud fuses with the duct in the dorsal bud to become the main pancreatic duct (duct of Wirsung), which drains the majority of the pancreas into the duodenum through the major papilla, or ampulla of Vater. The proximal duct of the dorsal bud forms the lesser or minor pancreatic duct (duct of Santorini) which drains into the duodenum through the minor papilla proximal to the ampulla of Vater.

Figure 52-1. A–D: Schematic drawings of the successive stages in the development of the pancreas from the fifth through the eighth weeks. E–G: Diagrammatic transverse sections through the duodenum and the developing pancreas. Growth and rotations (*arrows*) of the duodenum bring the ventral pancreatic bud toward the dorsal bud and they subsequently fuse. The bile duct initially attaches to the ventral aspect of the duodenum and is carried around to the dorsal aspect as the duodenum rotates. The main pancreatic duct is formed by the union of the distal part of the dorsal pancreatic duct and the entire ventral pancreatic duct.

The endocrine function of the pancreas begins during gestation, whereas the exocrine function does not begin until after birth. The first glucagon-producing cells are seen in 3-week-old embryos and the first islets appear at approximately 10 weeks. During this early developmental period, predominantly glucagon-positive islet cells initially appear in the tail of the pancreas. Early glucagon-positive endocrine cells convert to nonepithelial cells and lose connection with the lumen and tight junctions. Subsequently, there is a major amplification of endocrine cell numbers, particularly B cells, which produce insulin.

Figure 52-2. Anatomic configuration of the intrapancreatic ductal system. **A:** The classic anatomy is present in 60% of cases, where the accessory duct drains into the minor papilla and the main duct drains into the ampulla of Vater. **B:** The accessory pancreatic duct is blind and does not drain into the duodenum in 30% of cases. **C:** A lack of communication between the two ducts, which occurs in 10% of cases, is referred to as *pancreas divisum*. When this occurs the main pancreatic duct drains into the duodenum through the minor papilla. **D:** Pancreatogram obtained on ERCP through cannulation of the minor papilla in a patient with pancreas divisum; the main duct drains into the minor papilla. **E:** MRCP on the same patient. The main pancreatic duct drains into the minor papilla and the common bile duct drains into the ampulla of Vater.

Surgical Significance of Congenital Pancreatic Abnormalities

4 Abnormalities in the rotation and fusion of the pancreas during embryonic development can result in specific congenital anomalies that have surgical significance. In approximately 60% of people, rotation

and fusion occur normally resulting in the classic anatomy seen in [Figure 52-2A](#). The dorsal and ventral ducts fuse to form the main pancreatic duct which drains the majority of the pancreas into the ampulla of Vater. The lesser duct, formed from the proximal duct of the dorsal bud, drains into the duodenum at the minor papilla.

In approximately 30% of cases, the ventral and dorsal ducts fuse and drain normally into the duodenum at the ampulla of Vater. However, there is atrophy of the accessory or minor duct with a blind end and drainage into the duodenum ([Fig. 52-2B](#)). As this blind duct still communicates with the main pancreatic duct, this is of little to no clinical significance and most often found only at autopsy.

In 5% to 14% of cases, the fusion of the ventral and dorsal pancreatic ducts is incomplete ([Fig. 52-2C–E](#)).^{1–3} As a result of the incomplete fusion, the majority of the pancreas is drained into the duodenum through the minor papilla. This is called pancreas divisum. Only the small remnant duct of the ventral bud drains the uncinate process into the duodenum via the ampulla of Vater. Whether or not pancreas divisum causes pancreatitis and abdominal pain is unclear.^{1,4,5} It is often asymptomatic. However, mucosal stenosis at the minor papilla may lead to cystic dilatation of the dorsal duct resulting in pancreatitis and pain.^{1,6–8} Pancreatitis or abdominal pain due to pancreas divisum is a diagnosis of exclusion, and other etiologies for the pancreatitis should be thoroughly investigated. If no other causes of pancreatitis are identified in the setting of abdominal pain, elevated amylase levels, and pancreas divisum, the anomaly is considered causative and an endoscopic or operative papillotomy of the minor papilla and accessory duct is indicated. Recurrent acute pancreatitis or chronic pancreatitis with chronic pain attributed to pancreas divisum is most often seen in young females.

Annular pancreas is a rare congenital anomaly of the pancreas first recognized in 1818. Early autopsy and surgical series estimate the incidence to be approximately 3 in 20,000.^{9,10} However, with better imaging modalities such as computed tomography (CT), magnetic resonance cholangiopancreatography (MRCP), and endoscopy, the incidence is thought to be closer to 1 in 1,000.^{11–13} Annular pancreas is thought to result from abnormal fusion of the ventral pancreatic bud to the duodenum, leading to improper rotation of the ventral bud around the duodenum.¹⁴ This failure of rotation leads to a thin band of normal pancreatic parenchyma completely surrounding the second portion of the duodenum ([Fig. 52-3A–C](#)). This band is in continuity with the head of the pancreas and causes variable degrees of duodenal compression and stenosis. This abnormal ring of pancreatic tissue may contain a pancreatic duct. Therefore, the surgeon must be aware of this anomaly; if annular pancreas is incidentally encountered during an operation, it should not be divided. Division of the abnormal ring can result in pancreatic fistula or obstruction of pancreatic ductal drainage.

Figure 52-3. Annular pancreas. **A:** CT scan of a patient with annular pancreas. There is a ring of pancreatic tissue surrounding the duodenum, with a narrowed duodenal lumen. **B:** EGD image in the same patient. Note narrowing of the duodenal lumen with no mucosal lesion consistent with external compression by the annular pancreas. **C:** Intraoperative photo of an annular pancreas. Note the dilated duodenum after the pylorus, the ring of pancreatic tissue surrounding the duodenum just distal to the dilation, and the decompressed distal duodenum.

Annular pancreas can present at varying time points from in utero to adulthood.¹³ When diagnosed in utero, the most common presentation is polyhydramnios due to duodenal obstruction. Newborns present most commonly with duodenal obstruction shortly after birth, as evidenced by low birth weight and feeding intolerance. In people who present in utero or in childhood, it is more commonly associated with other congenital anomalies including Down syndrome, cardiac anomalies, and other intestinal anomalies. Duodenal bypass (duodenoduodenostomy or gastrojejunostomy) is the treatment of choice in children.

Fifty percent of cases of annular pancreas occur in adults. Adults are less likely to present significant obstruction and less likely to require surgical intervention. If they do present with obstruction, treatment is similar to that in children. In adults, annular pancreas is more commonly associated with pancreas divisum and pancreatic neoplasia than in children.¹³ Heterotopic pancreas is pancreatic tissue outside the bounds of the normal pancreas without anatomic or vascular connections to the pancreas itself. Heterotopic pancreas occurs in 0.5% to 14% of autopsy series. The heterotopic pancreatic tissue is functional and can occur in a variety of sites including the stomach, duodenum, ileum, umbilicus, colon, appendix, gallbladder, and even within a Meckel diverticulum. This tissue is usually submucosal and uniformly contains acini and ducts. Up to one-third contains islet cells. Heterotopic pancreas is usually an incidental finding, but can present with ulceration, obstruction, or intussusception, in which case treatment is directed at the presenting symptoms and may require resection. In incidental and asymptomatic cases, no treatment is required. The heterotopic pancreas is susceptible to the same diseases as normal pancreas and can even undergo malignant transformation.^{15,16}

EXOCRINE AND ENDOCRINE STRUCTURE

The exocrine structures of the pancreas account for 80% to 90% of the pancreatic mass while the endocrine structure accounts for approximately 2% of the pancreatic mass. The remainder of the pancreas comprises extracellular matrix, blood vessels, and major ductal structures.

Exocrine Structure

The exocrine structure of the pancreas is composed of two main components: the acinar cells and the ductal network. The acinar cells produce and secrete the enzymes and zymogens responsible for digestion. The acinar cells are pyramidal cells with an apex that faces the pancreatic ductal network. Approximately 20 to 40 acinar cells cluster together to form the functional unit called an acinus ([Fig. 52-4A,B](#)). Zymogen granules within the acinar cells contain the digestive enzymes for secretion into the ductal system. Located more centrally within the acinus, the centroacinar cell secretes alkaline fluid (pH 8.0) into the pancreatic ductal system. The acinus drains initially into small intercalated ducts, which join to form interlobular ducts that also secrete fluid and electrolytes ([Fig. 52-4A](#)). These interlobular ducts form secondary ducts that drain into the main pancreatic ductal system and eventually the duodenum at the ampulla of Vater.

Figure 52-4. Histologic anatomy of the acinus. **A:** Low-magnification view of a portion of the pancreas. **B:** High-magnification view of a single acinus. The acinar cells, containing zymogen granules, are pyramidal cells with an apex that faces the pancreatic ductal network. Twenty to 40 acinar cells that cluster together to form the functional unit called an acinus. The centroacinar cell, also present within the acinus, functions to secrete fluid and electrolytes of the correct pH into the pancreatic ductal system. The acinus drains into small intercalated ducts, which join to form interlobular ducts that also secrete fluid and electrolytes. These interlobular ducts form secondary ducts that drain into the main pancreatic duct.

Endocrine Structure

5 The pancreatic islet cells are of neural crest origin and part of the family of amine precursor uptake and decarboxylation (APUD) cells. Each pancreatic islet is approximately 40 to 900 μm and contains an average of 3,000 cells. The islets are composed of four cell types. These cell types are differentially distributed both throughout the pancreas and within the islets. [Table 52-1](#) describes the cell types, their hormonal products, and their location within the islet and the pancreas.

B (or beta) cells are located centrally within the islets. They constitute approximately 70% of the islet cell mass. The main secretory product of B cells is insulin, but they also excrete amylin and cholecystokinin. A (or alpha) cells and F cells are located peripherally within the islets and constitute 10% and 15% of the islet cell mass, respectively. Glucagon is secreted by A cells, which is the major counter-regulatory hormone to insulin in glucose homeostasis. F cells secrete pancreatic polypeptide. D cells are evenly distributed throughout the islet and constitute 5% of the islet cell mass.¹⁷ They can be further divided into D cells which secrete somatostatin and D₂ cells which secrete vasoactive intestinal peptide (VIP). E (or epsilon cells) and C cells comprise <1% of the islet mass and secrete substance P and serotonin. They are of minimal clinical significance.

6 The distribution of endocrine cell types is not uniform throughout the pancreas. B and D cells are concentrated in the tail of the pancreas, whereas A cells (as well as C and E cells) are evenly distributed and F cells are concentrated in the pancreatic head and uncinate process. As such, resection of the pancreatic body and tail removes more of the insulin-producing cells and is more likely to cause endocrine insufficiency (diabetes). This distribution also has clinical relevance with regard to the location of endocrine neoplasms when they occur.

The islet cells have a rich blood supply supporting their endocrine role. The afferent arteriole enters

the islet in an area of discontinuity in the non-B cells surrounding the periphery. The afferent arteriole then breaks into a capillary bed within the islet. Blood exits the islet through an efferent collecting venule. The hormones from the islet cells are secreted directly into this rich capillary network within the islet.

7 The most critical role of the pancreatic islet cells is the secretion of insulin and glucagon to maintain glucose homeostasis. Pancreatic endocrine secretion also regulates pancreatic exocrine secretion. Insulin stimulates pancreatic exocrine secretion, amino acid transport, and synthesis of protein and enzymes, whereas glucagon acts in a counter-regulatory fashion, inhibiting the same processes. The role of somatostatin is controversial. Somatostatin may have a direct inhibitory effect on pancreatic acinar cells, which possess somatostatin receptors. It may also act through an inhibitory effect on islet B cells.

PANCREATIC PHYSIOLOGY

Exocrine Function

The pancreas secretes 1.5 to 3 L of a pancreatic fluid daily. The enzymes and zymogens play a major role in the digestive activity of the gastrointestinal tract. Pancreatic fluid is alkaline (pH 7.6 to 9.0) and carries over 20 proteolytic enzymes and zymogens to the duodenum. The enzymes are released into the duodenum in their inactive state; the fluid serves to neutralize gastric acid and provides an optimal milieu for the function of these enzymes.

Pancreatic secretion is regulated via an intimate interaction of both hormonal and neural pathways that integrate the function of the pancreas, biliary tract, and small intestine. Vagal (parasympathetic) afferent and efferent pathways strongly affect pancreatic secretion. The secretion of enzyme-rich fluid is largely dependent on the vagal stimulation, whereas fluid and electrolyte secretion are more dependent on the direct hormonal effects of the secretin and cholecystikinin (CCK). Parasympathetic stimulation also causes the release of VIP, which also serves to stimulate secretin secretion.¹⁸

Table 52-1 Pancreatic Endocrine Cell Types

Cell Type	% Islet Cell Mass	Major Hormone Secreted	Location Within Islet	Location Within Pancreas	Associated Tumor Syndrome
A (alpha)	10%	Glucagon	Peripheral	Evenly distributed	Glucagonoma: necrolytic migratory erythema, diabetes, hypoaminoacidemia
B (beta)	70%	Insulin	Central	Body/Tail	Insulinoma: hypoglycemia and associated symptoms
D	5% ^a	Somatostatin	Evenly distributed	Body/Tail	Somatostatinoma: diabetes, gallstones, steatorrhea
D ₂	5% ^a	Vasoactive intestinal peptide (VIP)	Evenly distributed	Body/Tail	VIPoma: high-volume secretory diarrhea, hypokalemia, metabolic acidosis, hypochlorhydria
F	15%	Pancreatic polypeptide	Peripheral	Head and uncinate process	Treatment directed at presenting symptoms
E C	<1%	Substance P, serotonin	Evenly distributed	Evenly distributed	None
G	Not present in normal physiologic state	Gastrin, ACTH-related peptides	Not applicable	Head, uncinate process, duodenum	Gastrinoma: acid hypersecretion, gastric/duodenal ulcers, diarrhea

^aCombined D and D₂ mass.

Many neuropeptides also influence pancreatic secretion in an inhibitory fashion. These include somatostatin, pancreatic polypeptide, peptide YY, calcitonin gene-related peptides, neuropeptide Y, pancreastatin, enkephalin, glucagon, and galanin. While these neuropeptides are known to play a role in regulation of pancreatic secretion, the mechanisms of action and the intricate interplay between the neuropeptides is not fully understood.¹⁸

Bicarbonate Secretion

Bicarbonate is the most physiologically important ion secreted by the pancreas. Bicarbonate is formed from carbonic acid by the enzyme carbonic anhydrase. The secretion of water and electrolytes originates in the centroacinar and intercalated duct cells (Fig. 52-4). These cells secrete 20 mmol of

bicarbonate per liter in the basal state and up to 150 mmol/L in the maximally stimulated state.¹⁸ The bicarbonate secreted from the ductal cells is primarily derived from the plasma. Chloride efflux through the cystic fibrosis transmembrane conductance regulator (CFTR) leads to depolarization and bicarbonate entry through the sodium bicarbonate cotransporter.¹⁸ As a result, chloride secretion varies inversely with bicarbonate secretion; the sum of these two anions balances the sodium and potassium cations and remaining constant and equal to that of the plasma.

Both secretin and VIP stimulate bicarbonate secretion by increasing intracellular cyclic AMP, which acts on the CFTR.¹⁸ Gastric acid is the primary stimulus for release of secretin. Secretin is released from the duodenal mucosa in response to a duodenal lumen pH of less than 3.0 due to gastric acid.

The duodenum and jejunum release CCK in response to the presence of long-chain fatty acids, some essential amino acids (methionine, valine, phenylalanine, and tryptophan), and gastric acid. CCK is weak direct stimulator of bicarbonate secretion, but it acts as a neuromodulator and potentiates the stimulatory effects of secretin. Gastrin and acetylcholine are also weak stimulators of bicarbonate secretion.¹⁹ Bicarbonate secretion is inhibited by atropine (vagal stimulation) and can be reduced by 50% after truncal vagotomy.²⁰ Islet cell peptides including somatostatin, pancreatic polypeptide, glucagon, galanin, and pancreastatin are thought to inhibit exocrine secretion.

Enzyme Secretion

Pancreatic enzymes originate in the acinar cells, which are highly compartmentalized. Proteins are synthesized in the rough endoplasmic reticulum, processed in the Golgi apparatus, and then targeted to the appropriate cell compartment (zymogen granules, lysosomes, etc.). The acinar cells secrete enzymes that fall into three major enzyme groups: amylolytic enzymes, lipolytic enzymes, and proteolytic enzymes. Amylolytic enzymes such as amylase hydrolyze starch to oligosaccharides and the disaccharide maltose. Lipolytic enzymes such as lipase, phospholipase A, and cholesterol esterase function work in conjunction with bile salts to digest fats and cholesterol. Proteolytic enzymes include endopeptidases (trypsin and chymotrypsin) and exopeptidases (carboxypeptidase). Endopeptidases act on the internal peptide bonds of proteins and polypeptides and exopeptidases act on the free carboxy- and amino-terminal ends of proteins. Proteolytic enzymes are secreted as inactive precursors. Enterokinase cleaves the lysine–isoleucine bond in trypsinogen to create the active enzyme trypsin. Trypsin then activates the other proteolytic enzyme precursors.¹⁸

The different pancreatic enzymes are not secreted in fixed ratios. They change in response to dietary alterations and stimuli such as gastric acid, hormones, and neuropeptides. When enzyme secretion is absent or impaired, malabsorption or incomplete digestion occurs, leading to fat and protein loss through the gastrointestinal tract. This is seen in patients with acute and chronic pancreatitis (who have destruction of the exocrine pancreas) and in patients who have undergone surgical resection of all or part of the pancreas. These patients often present with weight loss and steatorrhea secondary to malabsorption of nutrients. These signs and symptoms can be corrected by oral replacement of pancreatic enzymes with meals.

The nervous system initiates pancreatic enzyme secretion. This involves extrinsic innervation by the vagus nerve and subsequent innervation by the intrapancreatic cholinergic fibers. The neurotransmitters, acetylcholine and gastrin-releasing peptide activate calcium-dependent release of zymogen granules.¹⁸ In addition, CCK is a predominant regulator of enzyme secretion, doing so through activation of specific membrane-bound receptors and calcium-dependent second messenger pathways. Secretin and VIP weakly stimulate acinar cell secretion directly, but also potentiate the effect of CCK on acinar cells (Fig. 52-5). Insulin is required locally and serves in a permissive role for secretin and CCK to promote exocrine secretion.¹⁸

Through the secretion of the three classes of enzymes, the pancreas regulates complete digestion of carbohydrates, fats, and proteins. Autodigestion of the pancreas by these proteolytic enzymes is prevented by packaging of proteases in an inactive precursor form and by the synthesis of protease inhibitors including pancreatic secretory trypsin inhibitor (PSTI), serine protease inhibitor, kazal type 1 (SPINK1), and protease serine 1 (PRSS1). These enzymes are found in the acinar cell and loss of these protective mechanisms can lead to activation, autodigestion, and acute pancreatitis. Mutations in the SPINK1 and PRSS1 genes are known to cause one of the aggressive familial forms of chronic pancreatitis, leading to recurrent episodes of pancreatitis, with associated exocrine and endocrine insufficiency.^{21,22}

Figure 52-5. Schematic diagram of the acinar cell, demonstrating receptors for exocrine secretagogues and their intracellular bases of action. Six distinct classes of receptors are known, with principal ligands shown. CCK, cholecystokinin; VIP, vasoactive intestinal peptide; CRGP, calcitonin gene-related peptide; DAG, diacylglycerol.

Table 52-2 Characteristic Results of Secretin Testing: Volume, Bicarbonate Concentration, and Enzyme Secretion Changes in Pancreatic Disease Processes

Disorder	Pattern	Total Volume	Maximum Bicarbonate Secretion	Enzyme Secretion
End-stage pancreatitis	Total insufficiency	Decreased	Decreased	Decreased
Advanced pancreatic cancer	Total insufficiency	Decreased	Decreased	Decreased
Chronic pancreatitis	Qualitative insufficiency	Normal	Decreased	Normal
Pancreatic Cancer	Quantitative insufficiency	Decreased	Normal	Normal
Malnutrition ^a	Isolated enzyme deficiency	Normal	Normal	Decreased
Hemochromatosis, Zollinger–Ellison syndrome, cirrhosis	Hypersecretion	Increased	Normal	Normal

^aCeliac disease, ulcerative colitis, and Crohn disease

Tests of Pancreatic Exocrine Function

8 Several tests are useful in the assessment of pancreatic exocrine function. Such tests are useful in both diagnosing and determining the etiology of exocrine insufficiency (chronic pancreatitis, malnutrition, cancer, and Zollinger–Ellison syndrome) (Table 52-2). Steatorrhea from pancreatic exocrine dysfunction is the result of lipase deficiency and is usually not present until lipase secretion is reduced by 90%. The secretin test, the dimethadione test (DMO) and the Lundh test require duodenal intubation. The classic test of pancreatic exocrine function is the secretin test.²³ A patient fasts overnight. A double-lumen tube is then placed in the duodenum. Basal collections are performed for 20 minutes and analyzed for total volume, bicarbonate output, and enzyme secretion. An intravenous bolus of 2 units of secretin per kilogram is given and four collections every 20 minutes are analyzed for volume, bicarbonate levels, and enzyme levels.

Normal values for the standard secretin stimulation test are 2.0 mL of pancreatic fluid per kilogram per hour, bicarbonate concentration of 80 mmol/L, bicarbonate output of >10 mmol/L in 1 hour, and

amylase secretion of 6 to 18 International Units/kg. The maximal bicarbonate concentration provides the greatest discrimination between normal subjects and patients with chronic pancreatitis.²⁴ The results of the secretin stimulation test for different pancreatic disease processes is shown in [Table 52-2](#).

The pancreas metabolizes the anticonvulsant drug trimethadione to its metabolite, DMO. After placing a double-lumen tube in the duodenum, patients are given 0.45 g of trimethadione three times daily for 3 days. Secretin is given through the double-lumen tube to maximally stimulate pancreatic secretion. To measure pancreatic exocrine function, the duodenal output of DMO is analyzed.²⁵

The Lundh test directly measures pancreatic enzyme secretion in response to a meal of carbohydrate, fat, and protein. A patient fasts overnight, then has a double-lumen duodenal tube placed. After basal duodenal fluid collection, patients are given a meal consisting of 18 g of corn oil, 15 g of casein, and 40 g of glucose in 300 mL of water. Duodenal fluid is collected every 30 minutes for 2 hours and analyzed for trypsin, amylase, and lipase. This test relies on endogenous secretin and CCK secretion and may be abnormal in diseases involving the intestinal mucosa.

N-benzoyl-L-tyrosyl paraaminobenzoic acid (BT-PABA) is cleaved by chymotrypsin to form paraaminobenzoic acid (PABA), which is then excreted in the urine. The PABA test is performed by administering 1 g of BT-PABA in 300 mL of water orally. Urine is then collected for 6 hours. Patients with chronic pancreatitis excrete less than 60% of the ingested dose of PT-PABA.

Suspected pancreatic exocrine dysfunction can also be confirmed giving patients a test meal and measuring serum levels of the islet cell hormone pancreatic polypeptide (PP). Basal and meal-stimulated levels of serum PP are reduced in severe chronic pancreatitis and after extensive pancreatic resection. After an overnight fast, a test meal of 20% protein, 40% fat, and 40% carbohydrate is ingested. The normal basal range of PP is 100 to 250 pg/mL. In severe chronic pancreatitis, the basal levels are often less than 50 pg/mL. The normal response to a meal is a rise in PP levels to 700 to 1,000 pg/mL for 2 to 3 hours after the meal. In severe disease, this response is decreased to less than 250 pg/mL. PP release depends on intact pancreatic innervation and can also be decreased after truncal vagotomy, antrectomy, or in the setting of diabetic autonomic neuropathy.

The triolein breath test is a noninvasive test of pancreatic exocrine insufficiency or malabsorption, but does not differentiate between the two.²⁶ 25 g of ¹⁴C-labeled corn oil (triglycerides) are given to the patient orally. The metabolite, ¹⁴C-carbon dioxide, can be measured in the breath 4 hours after administration. Patients with disorders of fat digestion or malabsorption exhale less than 3% of the dose per hour. The test can be repeated after pancreatic enzyme replacement. Patients with pancreatic insufficiency will achieve a normal rate of excretion of ¹⁴C-carbon dioxide, whereas patients with enteric disorders (malabsorption) show no improvement.

Many tests can help differentiate between steatorrhea caused by pancreatic exocrine insufficiency versus malabsorption ([Table 52-3](#)). The secretin test, the PABA test, and PP will be normal in intestinal malabsorption and abnormal in pancreatic insufficiency. The fecal fat test measures intraluminal digestion products. Fecal fat content is measured over a 24-hour time period. If the fecal fat is elevated to more than 20 g this indicates pancreatic insufficiency, whereas steatorrhea in the presence of low levels of fecal fat (<20 g) indicates intestinal dysfunction. A reduction of fecal fat can be used to demonstrate adequate replacement of pancreatic enzymes in patients with exocrine insufficiency. However, this test is time consuming and disliked by patients and pancreatic enzyme replacement is often titrated based on symptom relief if the clinical situation leads to a high index of suspicion for pancreatic exocrine insufficiency (i.e., long-standing chronic pancreatitis) or once the diagnosis of pancreatic insufficiency is made.

Table 52-3 Differential Diagnosis of Intestinal and Pancreatic Steatorrhea

Parameter	Intestinal Steatorrhea	Pancreatic Insufficiency
24-hr fecal fat	<20 g; soapy consistency	>20 g; only seepage
D-xylose	Abnormal (low)	Normal
Secretin test	Normal	Abnormal
Small bowel series	Abnormal	Normal
Small bowel biopsy	Abnormal	Normal
PABA test	Normal	Abnormal
PP response to meal	Normal	Abnormal
Vitamin B ₁₂ and folate	Abnormal (low)	Normal
Treatment with pancreatic enzymes	No change	Improvement

Serum amylase, lipase, and trypsinogen are not elevated in the physiologic state. As amylase is found in organs other than the pancreas (salivary glands, liver, small intestine, kidneys, and fallopian tubes), serum amylase levels may be elevated in both pancreatic and nonpancreatic diseases (Table 52-4). When pancreatic disease is suspected, the measurement of serum amylase and lipase levels serve as a useful screening test. Assays for the isoenzymes of amylase can be performed, but are unreliable in determining whether the source of amylase is pancreatic or nonpancreatic and are not widely used. It has been shown that serum lipase is a more accurate biomarker of acute pancreatitis than serum amylase, with 19% of patients with acute pancreatitis having normal serum amylase levels, but only 3% having normal serum lipase levels.²⁷ Unlike amylase and lipase, serum trypsinogen is made only by the pancreas and may serve as a better marker for acute pancreatitis. Trypsinogen can also be measured in the urine and serves as a specific screening test for acute pancreatitis.^{28,29} All three markers are cleared by the kidneys so in the setting of acute renal failure, all may be falsely elevated. These levels do not measure actual endocrine function, but are commonly used to diagnose acute pancreatitis and monitor its resolution.

In the case of acute pancreatitis, serum amylase and lipase levels are usually elevated and peak within 24 hours of the onset of symptoms. They return to normal within 2 to 4 days if the inflammation resolves. In cases of severe necrotizing pancreatitis, pancreatic ductal obstruction, and pseudocyst formation, amylase and lipase levels can remain elevated for much longer periods of time. In this case, elevated levels often reflect amylase-rich fluid within peripancreatic collections and not ongoing acute inflammation.

While amylase and lipase levels are elevated in over 85% of patients with acute pancreatitis, their elevation is far less common in chronic pancreatitis, where the exocrine function of the pancreas may be impaired. Amylase levels may be normal in patients with acute pancreatitis if there is a delay in their diagnosis or if their pancreatitis is related to hypertriglyceridemia, which can falsely decrease the serum amylase levels.²⁴

Endocrine Function

The primary function of the endocrine pancreas is regulation of carbohydrate metabolism, primarily through regulation of insulin and glucagon secretion through a variety of feedback and regulatory mechanisms. Insulin promotes glucose transport into cells, inhibits glycogenolysis and fatty acid breakdown, and stimulates protein synthesis. Glucagon is the major counter-regulatory hormone to insulin. Glucagon secretion leads to elevated blood glucose levels through stimulation of glycogenolysis and gluconeogenesis.

Insulin Synthesis, Secretion, and Action

Insulin is a 56-amino-acid polypeptide with a molecular weight of 6 kD. It consists of two polypeptide chains (A and B) joined by two disulfide bridges. Insulin is synthesized by the B cells within the islets of Langerhans. Insulin is an anabolic hormone, promoting glucose transport into all cells except B cells, hepatocytes, and central nervous system cells. It also inhibits glycogenolysis and fatty acid breakdown but stimulates protein synthesis.

Table 52-4 Pancreatic and Nonpancreatic Causes of Hyperamylasemia

Pancreatic Diseases Causing Elevated Amylase Levels
Acute, uncomplicated pancreatitis
Pancreatic pseudocyst
Acute peripancreatic fluid collections
Pancreatic ascites
Pancreatic necrosis and/or abscess (infected pancreatic necrosis)
Pancreatic injury/trauma
Ductal obstruction in pancreatic cancer, pancreatic cystic neoplasms, or chronic pancreatitis
Nonpancreatic Diseases Causing Elevated Amylase Levels
Perforated duodenal ulcer
Duodenal ulcer penetrating pancreas
Small bowel obstruction
Ruptured ectopic pregnancy
Peritonitis
Salivary gland lesions (mumps, salivary duct stones, sialadenitis, iatrogenic ductal obstruction)
Other cancers (lung, esophagus, breast, ovarian)
Burns
Diabetic ketoacidosis
Renal insufficiency
Pregnancy

Figure 52-6. Synthesis of insulin. Proinsulin is synthesized by the endoplasmic reticulum and packaged within the secretory granules of the B cell. There it is cleaved into insulin and C peptide. Equimolar amounts of insulin and C peptide are secreted into the bloodstream.

The amino acid sequence varies among species, but the location of the disulfide bridges are highly conserved and are critical for its biologic activity. When pancreatic B cells are stimulated, proinsulin (precursor peptide to insulin) is synthesized in the endoplasmic reticulum and transported to the Golgi. In the Golgi, the proinsulin is packaged into granules where it is cleaved into insulin and the residual connecting peptide, C peptide (Fig. 52-6). The granules are then released directly into the bloodstream. Defects in the synthesis and cleavage of insulin can lead to rare forms of diabetes mellitus such as Wakayama syndrome and proinsulin syndrome.³⁰

The secretion of insulin is tightly regulated by nutrient, neural, and hormonal factors. In response to glucose, the predominant nutrient regulator, insulin is secreted in two phases. The first phase is a short burst of stored insulin that lasts 4 to 6 minutes. This is followed by a sustained secretion of insulin, which requires active synthesis of the hormone within the islet cell. The B cell is sensitive to even small changes in glucose concentration and is maximally stimulated at concentrations of 400 to 500 mg/dL. Insulin is released in an oscillatory or pulsatile pattern controlled by an internal pacemaker which is present even in isolated islet cells.³¹ Insulin has a short half-life of 7 to 10 minutes after secretion. Forty percent to 70% of insulin secreted into the portal venous system is metabolized by hepatocytes on the first pass through the liver. Excess insulin is then slowly metabolized by the liver, kidneys, and skeletal muscles. Insulin is not taken up by brain cells or red blood cells.

Insulin binds to a 300-kD glycoprotein cell surface receptor. Stimulation of the insulin receptor is dependent upon insulin concentration. Insulin resistance, present in type II diabetes, can be the result of decreased numbers of receptors or a decreased affinity for insulin. Glucose is actively transported across

cell membranes throughout the body by glucose transporters. There are several classes of glucose transporters with varying affinities for glucose. The GLUT-2 transporter located on B cells has a low affinity for glucose. This results in low rates of transport at physiologic concentrations of glucose but an increased rate of transport at higher concentrations, with subsequent higher insulin secretion rates.³² The loss of B-cell GLUT-2 transporter can contribute to the development of diabetes mellitus.³³

Through the enteroinsular axis, the release of enteric hormones in response to glucose potentiates insulin secretion. As such, orally administered glucose has a greater effect on insulin secretion than an equivalent amount of glucose administered intravenously. Gastric inhibitory polypeptide (GIP) is an important regulator of insulin secretion.³⁴ Additional gut peptides and hormones that stimulate insulin secretion include glucagon, glucagon-like peptide-1, and CCK, while somatostatin, amylin, and pancreastatin inhibit insulin secretion. Nutrients including certain amino acids (arginine, lysine, and leucine) and free fatty acids also regulate insulin secretion. Sulfonylurea compounds, which act independently of glucose concentration, also stimulate insulin secretion and are used in the treatment of type II diabetes, where the primary defect is peripheral insulin resistance and not insulin production or decreased islet-cell mass.

Parasympathetic and sympathetic innervation also influences B-cell activity. Both cholinergic and b-sympathetic fibers stimulate insulin secretion, whereas s-sympathetic fibers are inhibitory. A loss of pancreatic innervation in the setting of pancreatic transplantation can therefore result in changes in the pattern and quality of insulin secretion. There is a significant secretory reserve of insulin within the pancreas. Destruction or removal of 80% of the pancreatic islet cell mass is necessary before endocrine dysfunction becomes clinically apparent in the form of type I (insulin-dependent) diabetes.³⁵

Glucagon Synthesis, Secretion, and Action

Glucagon, secreted by the islet A, is a single-chain, 29-amino-acid polypeptide with a molecular weight of 3.5 kD. Glucagon is the major catabolic hormone, elevating blood glucose levels through stimulation of glycogenolysis and gluconeogenesis in the liver. Like epinephrine, cortisol, and growth hormone, glucagon is considered a stress hormone because it increases metabolic fuel in the form of glucose during stress. Secretion of pancreatic glucagon is tightly controlled by neural, hormonal, and nutrient factors. Like insulin, glucose is the primary regulator, but the two hormones respond to glucose in reciprocal fashion. Glucose has a strong suppressive effect on glucagon secretion. The two hormones are counter-regulatory and function together to tightly control blood glucose levels. Excess glucagon can lead to hyperglycemia, whereas insufficient glucagon can lead to profound hypoglycemia. For this reason, the diabetes resulting from total pancreatectomy is very brittle and difficult to control due to the lack of endogenous glucagon to balance exogenously administered insulin.

Glucagon secretion is also stimulated by the amino acids arginine and alanine. Through paracrine effects within the islets, both insulin and somatostatin have a suppressive effect on glucagon secretion. The neural regulation of glucagon parallels that of insulin, with cholinergic fibers being strongly stimulatory, b-sympathetic fibers being weakly stimulatory, and a-sympathetic fibers being inhibitory. Dysfunctional A-cell secretion of glucagon may play a role in the elevation of blood sugar in diabetes.

Somatostatin Synthesis, Secretion, and Action

9 Somatostatin is a 14-amino-acid polypeptide weighing 1.6 kD. The role of endogenous somatostatin is unclear; it has not been proven to directly influence the secretion of other peptide hormones from islet cells. However, exogenous administration of somatostatin has been shown to inhibit the release of insulin, glucagon, growth hormone, and pancreatic polypeptide. Exogenous somatostatin administration has also been shown to inhibit gastric, pancreatic, and biliary secretion.

Both short- and long-acting synthetic peptides that mimic somatostatin pharmacologically have been developed. Somatostatin analogues are more potent inhibitors of growth hormone, glucagon, and insulin secretion than the natural hormone. They have been used to treat both exocrine and endocrine disorders of the pancreas. For example, in hormone-producing islet cell tumors which express somatostatin receptors, octreotide can effectively suppress the hormonal symptoms associated with the disease process and slow the progression of tumors.³⁶ There has been significant debate about the role of prophylactic somatostatin analogs in the prevention of pancreatic fistula formation after pancreatic surgery. A 2007 meta-analysis has shown that prophylactic octreotide reduces pancreatic fistula formation following elective pancreatic surgery³⁷ and a more recent randomized, controlled trial demonstrated that pasireotide given before surgery and for 7 days after surgery reduced the incidence of clinically significant postoperative fistulas, leaks, and abscesses.³⁸ A recent meta-analysis of pooled

data from randomized trials failed to show any advantage of somatostatin analogs for accelerating fistula closure after pancreatic surgery.³⁹

Pancreatic Polypeptide Synthesis, Secretion, and Action

Pancreatic polypeptide is a 36-amino-acid polypeptide secreted by the F cells of the pancreatic islet. The physiologic role of pancreatic polypeptide remains unclear. It has been shown to inhibit pancreatic exocrine secretion and gallbladder emptying. Cholinergic innervation predominantly regulates pancreatic polypeptide secretion. In diabetes and normal aging pancreatic polypeptide secretion is increased resulting in increased circulating pancreatic polypeptide levels.

Other Peptide Products

Other peptides are secreted within the pancreatic islet. These include neuropeptides such as VIP, galanin, amylin, pancreastatin, chromogranin A, and serotonin, which are believed to play a role in the regulation of islet cell secretion. Amylin, a 36-amino-acid polypeptide, is secreted by the B cells, but not in equimolar amounts to proinsulin. Amylin inhibits secretion of insulin and its uptake in the periphery. Amylin has been found to be deposited in the pancreas of patients with type II diabetes and has been implicated in the pathogenesis of the disease. Pancreastatin is another peptide found in large amounts in the pancreas. It is a derivative of chromogranin A, but its physiologic significance is unknown. Chromogranin A is produced by most neuroendocrine tumors and is a good marker for diagnosis and recurrence of pancreatic neuroendocrine tumors.

Tests of Pancreatic Endocrine Function

The most widely used tests of pancreatic endocrine function measure the body's ability to utilize glucose. The oral glucose tolerance test provides an indirect assessment of the insulin response to an oral glucose load; it measures the glucose profile and not the actual insulin response. After an overnight fast, two basal blood samples are drawn and glucose levels are analyzed. Patients are then given an oral glucose load of 40 g/m² over 10 minutes. Blood samples are then drawn every 30 minutes for 2 hours. The fasting glucose level should be less than 110 mg/dL. Fasting levels between 110 and 126 mg/dL are considered borderline, and fasting levels above 126 mg/dL are diagnostic of diabetes. The 2-hour glucose level should be below 140 mg/dL. Two-hour levels between 140 and 200 mg/dL are borderline, and 2-hour levels over 200 mg/dL are again diagnostic of diabetes mellitus. The test takes into account the gastrointestinal influences of glucose metabolism and can be affected by antecedent diet, drug use, exercise, and patient age.

The intravenous glucose tolerance test can be used to eliminate gastrointestinal influences on glucose metabolism. After basal glucose levels are obtained, this test is performed in similar fashion to the oral glucose tolerance test, except the glucose load is delivered as an intravenous bolus of 0.5 g/kg over 2 to 5 minutes. Blood is then drawn every 10 minutes for an hour. The disappearance of glucose per minute (K value) is calculated. A K value of 1.5 or higher is normal. The results are age adjusted, as the response to the intravenous glucose load decreases with age.

An insulinoma is a pancreatic neuroendocrine tumor that secretes insulin. The gold standard for diagnosis of insulinoma is the 72-hour monitored fast. This test documents Whipple triad of hypoglycemia, neuroglycopenic symptoms concurrent with hypoglycemia, and resolution of symptoms with administration of glucose. It also allows the clinic to rule out surreptitious administration of exogenous insulin. Within the B cell, proinsulin is cleaved into insulin and C-peptide prior to secretion. Therefore, both insulin and C-peptide levels can be measured in the blood stream and should be present in a 1:1 ratio. Surreptitious administration of exogenous insulin can be differentiated from insulinoma by the absence of C-peptide in the case of the exogenously administered insulin. Patients are fasted in a monitored setting. All nonessential medications are stopped and patients can only drink water, black, decaffeinated coffee, and diet sodas. Glucose and insulin levels as well as neuroglycopenic symptoms are closely monitored. The criteria for discontinuing the fast include serum glucose levels less than 45 mg/dL and the patient must be symptomatic. The 72-hour fast is highly sensitive for insulinoma and a patient rarely finishes this test without an unequivocal diagnosis. Urine should also be screened for the presence of sulfonylureas and other oral hypoglycemic medications.

The intravenous arginine test and tolbutamide response test are used to help in diagnosis of more rare hormone-secreting pancreatic neuroendocrine tumors. After an overnight fast, a patient is given a 30-minute intravenous infusion of 0.5 g/kg of arginine, which stimulates secretion of islet cell hormones. Blood samples are taken every 10 minutes and radioimmunoassays are performed for the hormone in

question. This test is most useful for glucagon-secreting tumors and is not commonly used. Elevations of plasma glucagon levels to over 400 pg/mL are diagnostic for glucagonoma.

Tolbutamide is a sulfonylurea that stimulates insulin secretion and secretion of other pancreatic endocrine hormones. After fasting overnight, blood samples are drawn and a patient is given 1 g of tolbutamide intravenously. Blood glucose is monitored for 1 hour and blood samples are drawn to determine levels of the hormone of interest. Sustained hypoglycemia with hypersecretion of insulin is diagnostic of insulinoma. Somatostatin levels more than twice as high as the normal values of the particular assay used are considered diagnostic of somatostatinoma.

PANCREATIC ANATOMY

The pancreas lies in the retroperitoneum at the level of the second lumbar vertebrae. It lies obliquely and transversely from its most caudal point at the duodenal C-loop on the right to its most cranial point in the splenic hilum on the left. The pancreas is composed of four anatomic parts: the head (including the uncinate process), the neck, the body, and the tail (Fig. 52-7).

Figure 52-7. Normal pancreatic anatomy. The pancreatic head lies within the C-loop of the duodenum. The main pancreatic duct and common bile duct run through the head of the pancreas and drain into the duodenum at the ampulla of Vater. The superior mesenteric artery and vein lie posterior to the pancreatic neck.

Relationship to Adjacent Structures

The pancreatic head is further subdivided into the head and uncinate process. The head and uncinate process lie within the C-loop of the duodenum and include all the pancreatic parenchyma to the right of the superior mesenteric vessels. The pancreatic head is attached to the medial aspect of the descending and third portion of the duodenum and the two organs share a blood supply. The uncinate process projects from the inferior portion of the pancreatic head medially to the left, then posterior to the superior mesenteric vessels. The inferior vena cava, right renal artery and vein, and left renal vein lie posterior to the uncinate process and pancreatic head. The bile duct runs through the posterior and superior aspect of the pancreatic head, joining the pancreatic duct and draining into the duodenum medially at the ampulla of Vater (Fig. 52-7).

The pancreatic neck is the portion of pancreatic tissue that overlies the superior mesenteric artery and vein anteriorly. The anterior surface of the pancreatic neck lies directly posterior to the pylorus of the stomach. The body of the pancreas continues left from the pancreatic neck. The anterior surface of the pancreatic neck, body, and tail are covered with peritoneum and forms the floor of the omental bursa within the lesser sac. The stomach overlies the pancreatic body/lesser sac anteriorly. The posterior surface of the pancreatic body is not peritonealized and directly contacts the aorta, left adrenal gland, left kidney, and left renal artery and vein. The body of the pancreas is the portion overlying the second lumbar vertebrae. The tail of the pancreas begins anterior to the left kidney and extends superolaterally

to the hilum of the spleen. The splenic artery and vein run along the posterior surface of the pancreas. The tail of the pancreas is in close proximity to the spleen and splenic flexure of the colon.

Pancreatic Ductal Anatomy

The main pancreatic duct, or duct of Wirsung, begins in the pancreatic tail. It most commonly runs within the posterior aspect of the pancreatic parenchyma, midway between the superior and inferior border of the gland. In the head of the pancreas, the pancreatic duct turns inferiorly at the genu of the pancreatic duct and joins the common bile duct, draining into the second portion of the duodenum at the ampulla of Vater. A common channel may exist between the common bile duct and main pancreatic duct and it varies in length across the population. At the level of the ampulla of Vater, the pancreatic duct is anterior and inferior to the common bile duct. At the ampulla of Vater, the sphincter of Oddi prevents reflux of duodenal contents into the bile duct and pancreatic duct. This sphincter of Oddi is controlled by a variety of neural and hormonal factors that regulate relaxation and constriction.

A normal main pancreatic duct is 2 to 4 mm in diameter and has a ductal pressure of approximately 15 to 30 mm Hg. This is higher than the pressure in the common bile duct (7 to 17 mm Hg) and serves to prevent reflux of bile into the pancreatic ductal system. There are over 20 side branches of the main pancreatic duct throughout the pancreas providing drainage of acinar units. The accessory pancreatic duct, or duct of Santorini, is more variable than the main pancreatic duct. It typically drains the uncinate process and inferior portion of the pancreatic head into the duodenum at the minor papilla, proximal to the ampulla of Vater.

Arterial Blood Supply

The pancreatic blood supply arises from the celiac axis and superior mesenteric artery. The celiac axis arises from the abdominal aorta and most commonly gives rise to the splenic artery, the left gastric artery, and the common hepatic artery ([Fig. 52-8A](#)). The splenic artery courses along the posterior surface of the pancreatic body and tail and gives rise to more than 10 branches which supply the pancreatic body and tail. The first branch of the splenic artery is the dorsal pancreatic artery; it arises close to the origin of the splenic artery and supplies blood to the proximal body. Further distally, the great pancreatic artery supplies the midportion of the body and the caudal pancreatic artery supplies the pancreatic tail.

The head of the pancreas is supplied by both the celiac and superior mesenteric artery (SMA). The gastroduodenal artery is the first branch off the common hepatic artery. Distal to the first portion of the duodenum, the gastroduodenal artery becomes the superior pancreaticoduodenal artery and divides into anterior and posterior branches. The SMA gives rise to the inferior pancreaticoduodenal artery, which also divides into anterior and posterior branches. The inferior and superior pancreaticoduodenal arcades form an extensive collateral network with the superior pancreaticoduodenal arcades, supplying both the duodenum and head of the pancreas. Anteriorly these arcades lie in the groove between the pancreas and duodenum. Posteriorly, they cross the common bile duct. The arterial blood supply of ampulla of Vater is from three pedicles off the superior and inferior pancreaticoduodenal arteries. The posterior pedicle, located at 11 o'clock, arises from the superior pancreaticoduodenal artery. The ventral commissural pedicle, located at 1 o'clock, arises from both arcades. Finally, the inferior pedicle at 6 o'clock arises from the anterior branch of the inferior pancreaticoduodenal artery. Near the head of the pancreas, branches arising from the splenic artery form collaterals with the inferior pancreaticoduodenal arcades.

Figure 52-8. 3D CT reconstructions of (A) Normal arterial supply to the pancreas, (B) Replaced right hepatic artery arising from the superior mesenteric artery, (C) Replaced common hepatic artery arising from the superior mesenteric artery and (D) Replaced left hepatic artery arising from the splenic artery.

Variations or anomalies in the pancreatic and biliary blood supply are found in 20% to 30% of people. In most cases, all or part of the hepatic arterial blood supply does not arise from the celiac axis. As much of the pancreatic blood supply is derived from the hepatic arterial blood supply, these variations lead to variations in the pancreatic blood supply. In approximately 20% of patients, the replaced right hepatic artery arises from the superior mesenteric artery (Fig. 52-8B) in the retropancreatic position and traverses the upper edge of the uncinate process, then runs posterolateral to the portal vein. In this case, a pulse remains in the hepatoduodenal ligament and the gastroduodenal artery can arise from the replaced right or the left hepatic artery. The right hepatic artery can also originate from the right gastric in 2% of cases or from the gastroduodenal artery in 6% of cases.

The entire hepatic arterial supply can be replaced, with the common hepatic artery originating from the SMA instead of the celiac axis (Fig. 52-8C). In this case, there is no hepatic arterial pulse medially in the hepatoduodenal ligament. The replaced common hepatic artery runs anterior to the portal vein, but posterior to the bile duct and gives rise to a gastroduodenal branch, which is also posterior to the bile duct. In approximately 10% of cases, the left hepatic artery can be aberrant, most commonly arising from the left gastric artery instead of the proper hepatic artery.

Venous Drainage

The venous drainage of the pancreas follows the arterial blood supply and is eventually returned to the portal circulation and delivered back to the liver. There are four main routes of venous drainage in the pancreas. In the pancreatic head the superior venous arcades drain either directly into the portal vein superiorly or laterally. The anterior and inferior pancreaticoduodenal arcades drain directly into the infrapancreatic SMV. There are rarely any anterior branches from the pancreatic head and neck into the

superior mesenteric and portal veins. When they do occur, it is most commonly at the superior border of the pancreatic neck.

The body and tail of the pancreas has many venous tributaries that drain into the splenic vein, which joins the SMV posterior to the pancreatic neck forming the portal vein (PV). The three named tributaries of the splenic are the inferior pancreatic vein, the caudal pancreatic vein, and the great pancreatic vein. The inferior mesenteric vein (IMV) does not drain the pancreas, but joins the splenic vein posterior to the pancreatic body. The PV then drains the intestinal blood supply to the liver.

Lymphatic Drainage

Throughout the pancreas there is a rich periacinar network of lymphatic vessels which drain to five major nodal groups: superior, inferior, anterior, posterior, and splenic.⁴⁰ The superior nodal group runs along the superior border of the pancreas and celiac trunk. They drain the superior portion of the pancreatic head. The inferior nodal group along the inferior border of the head and body of the pancreas drain the inferior pancreatic head and uncinate process, eventually draining to the superior mesenteric and paraaortic lymph nodes. The anterior lymphatics drain to the prepyloric and infrapyloric nodes. The posterior lymph nodes include the distal common bile duct and ampullary lymphatics and drain directly into the paraaortic lymph nodes. Finally, the splenic lymph nodes drain the lymphatics of the pancreatic body and tail into the interceliomesenteric lymph nodes.

The Japanese Pancreas Society has classified the pancreatic lymphatic drainage into 18 lymph node stations (Table 52-5).⁴² The greater and lesser curves of the stomach drain into lymph node stations 1 through 4. The anterior lymphatics described above drain into lymph node stations 5 and 6. The superior nodal group includes lymph node stations 7 through 9 along the left gastric artery, common hepatic artery, and celiac axis. The posterior lymph nodes include lymph node stations 12 (and all subdivisions) and 13, while the inferior nodal group comprises stations 14 through 17. The splenic lymph node group corresponds to Japanese lymph node stations 10 and 11.

Innervation

The innervation to the pancreas is derived from the vagus and thoracic splanchnic nerves as well as peptidergic neurons that secrete amines and peptides.⁴³ Parasympathetic and sympathetic fibers for ganglia along the celiac axis and superior mesenteric artery, which give rise to the pancreatic branches reach the pancreas by passing along the arteries from the celiac axis and superior mesenteric arteries. The parasympathetic nerves stimulate both exocrine and endocrine secretion, while the sympathetic fibers have a predominantly inhibitory effect (Fig. 52-9).⁴⁴ The peptidergic neurons secrete hormones including somatostatin, VIP, calcitonin gene-related peptide (CGRP), and galanin. While the peptidergic neurons influence exocrine and endocrine secretion, their precise physiologic role is unclear. The pancreas also has a rich network of afferent sensory fibers.

Table 52-5 Japanese Lymph Node Stations

Station Number	Name	Standard	Radical
3	Gastric lesser curve	No ^a	Yes ^b
4	Gastric greater curve	No ^a	Yes ^b
5	Superior pyloric	No ^a	Yes
6	Inferior pyloric	No ^a	Yes
8	Common hepatic artery	No	No
9	Celiac origin	No	Yes ^c
12	HEPATODUODENAL LIGAMENT		
12a2	Proper hepatic artery near GDA	No ^d	No ^d
12b2	Bile duct below cystic duct	Yes ^e	Yes ^e
12c	Around cystic duct	Yes	Yes
12p2	Retro portal vein below cystic duct	No ^d	No ^d
13	Posterior pancreaticoduodenal	Yes	Yes
14	SMA AND SMV NODES		
14a	Origin of SMA	No	No
14b	Right side of SMA	Yes ^e	Yes ^e
14c	Anterior SMA at middle colic	No	No
14d	Left side of SMA at first jejunal branch	No	No
14v	SMV nodes	Yes ^e	Yes ^e
16	AORTOCAVAL NODES		
16a2	Celiac to left renal vein	No	Yes ^f
16b1	Left renal vein to IMA	No	Yes
17	Anterior pancreaticoduodenal	Yes	Yes

^aUnless a distal gastrectomy is performed as part of standard resection.
^bSome of these nodes may accompany the distal gastrectomy specimen.
^cSampled only.

SURGICAL SIGNIFICANCE OF PANCREATIC ANATOMY

10 Knowledge of the anatomy and anatomical variants can give clues to the diagnosis of pancreatic disease based on signs and symptoms. In addition, an understanding of the pancreatic anatomy in relation to adjacent structures is essential when performing operative procedures on the pancreas or surrounding structures including the duodenum, bile duct, and spleen.

Figure 52-9. Schematic diagram of the neurohormonal control of the exocrine cells. Visceral receptors line the ductule system and carry the sensation of pain to the spinal cord. Sympathetic fibers first synapse in the celiac plexus after traveling through the thoracic ganglia and splanchnic nerves. Postganglionic fibers then synapse on intrapancreatic arterioles. Parasympathetic preganglionic fibers travel through the celiac plexus after leaving the vagus nerves and course with vessels and ducts to synapse on postganglionic fibers near acinar cells, islet cells, and smooth muscle cells of major ducts. Stimulation of these parasympathetic fibers results in an immediate release of pancreatic enzymes. Secretin and CCK first enter the pancreas through the capillary network of the islet cells, and then enter the separate capillary network of the acinar tissue through the insuloacinar portal vessels. Glucagon, somatostatin, pancreatic polypeptide, and insulin from the islets cells reach the acinar tissue immediately after release. In this way, the islet cells can influence the acinar tissue responses to CCK and secretin.

Pancreatic Anatomy and Pancreatic Cancer

Approximately, 75% of pancreatic adenocarcinomas occur in the pancreatic head at the genu of the pancreatic duct.⁴⁵ As a result, people who develop cancer in the head of the pancreas most commonly present with obstructive jaundice secondary to occlusion of the intrapancreatic bile duct by tumor, leading to earlier diagnosis. People with body and tail tumors present with abdominal pain and other vague abdominal symptoms, often leading to a delay in diagnosis. Nearly 85% of resected pancreatic tumors are in the head, neck, or uncinate process of the pancreas.⁴⁶

Similarly, patients with cancer in the pancreatic head often have invasion of the adjacent duodenum. They may present with or develop signs and symptoms of duodenal or gastric outlet obstruction. In patients with unresectable disease, late gastric outlet obstruction in patients requiring gastrojejunostomy or duodenal stenting occurs in 10% to 20% of patients. A prospective, randomized trial demonstrated that the addition of prophylactic gastrojejunostomy in addition to hepaticojejunostomy significantly reduced gastric outlet obstruction in patients with unresectable disease undergoing open biliary bypass.⁴⁷ However, in the modern era, biliary stenting is so effective that operative hepaticojejunostomy for unresectable disease is rarely indicated. In the setting of isolated gastric outlet obstruction in unresectable disease, duodenal stenting is an option. When successful this can avoid surgery and its negative impact on the remaining quality of life. In a meta-analysis of trials

comparing endoscopic stenting to gastrojejunostomy, stenting was associated with shorter time to oral intake and shorter length of stay, with similar complication rates, and decreased mortality.⁴⁸

11 The ability to resect a pancreatic cancer depends on the presence or absence of metastatic disease and the extent of local vascular involvement. Pancreatic cancers are classified as resectable, borderline resectable, or unresectable (including locally advanced unresectable disease and metastatic disease). [Table 52-6](#) shows the 2014 National Comprehensive Cancer Network definitions for resectable, borderline resectable, and unresectable disease.⁴⁹ Tumors are considered resectable if they have: (1) no distant metastases, (2) no radiographic evidence of SMV or PV distortion, and (3) clear fat planes around the celiac axis, hepatic artery, and SMA ([Fig. 52-10A](#)).

Table 52-6 Criteria for Resectability in Pancreatic Cancer

Resectability Status	Definition ⁴⁹
Resectable	No distant metastases No radiographic evidence of superior mesenteric vein (SMV) or portal vein (PV) distortion Clear fat planes around the superior mesenteric artery (SMA), hepatic artery, and celiac axis
Borderline Resectable	No distant metastases Venous involvement of the SMV or PV with distortion, narrowing, or occlusion of the vein with anatomic options for safe resection and reconstruction Gastroduodenal artery encasement up to the hepatic artery with short segment encasement or abutment of the hepatic artery without involvement of the celiac axis Tumor abutment of SMA <180 degrees the circumference of the vessel
Locally advanced/unresectable	No distant metastases >180 degrees SMA involvement Invasion of the celiac axis Invasion or encasement of the aorta or inferior vena cava (IVC) Unreconstructable PV/SMV occlusion
Metastatic	Distant metastases (liver, lung, lymph nodes beyond the field of resection)

Tumors are considered borderline resectable if they have: (1) no distant metastases, (2) venous involvement of the SMV or PV with distortion or narrowing of the vein or occlusion of the vein with suitable vessel proximal and distal, allowing for safe resection and replacement, (3) gastroduodenal artery encasement up to the hepatic artery with either short segment encasement or direct abutment of the hepatic artery, without extension to the celiac axis, and (4) tumor abutment of the SMA not to exceed greater than 180 degrees of the circumference of the vessel wall ([Fig. 52-10B](#)).

Tumors are considered to be locally unresectable if there is: (1) no distant metastatic disease, (2) greater than 180 degrees SMA encasement, (3) any celiac axis abutment, (4) unreconstructable SMV/portal occlusion, (5) invasion or encasement of the aorta or inferior vena cava (IVC), and (6) nodal involvement outside the field of resection. Patients with any distant metastatic disease, most commonly to the liver or lymph nodes outside the field of resection, or the presence of peritoneal carcinomatosis are considered unresectable.

Pancreatic head cancers may also involve adjacent organs including the hepatic flexure of the colon, the gallbladder, or the stomach. If there are no distant metastases, resection of these organs *en bloc* is indicated. For cancers in the body and tail without distant metastasis, involvement of the splenic artery and/or vein does not preclude resection as these vessels are normally taken during the operation. However, involvement of the celiac axis or superior mesenteric artery precludes resection. Involvement of adjacent organs including the left kidney, left adrenal, spleen, and left colon can be resected if involved with tumor and there is no distant disease.

Knowledge of the normal pancreatic blood supply is critical in order to perform an adequate cancer operation. As the duodenum and head of pancreas share a blood supply, it is necessary to remove these organs *en bloc* when performing an operation for carcinoma. While the duodenum can be preserved in resections performed for benign disease (duodenum-preserving pancreatic head resection), this is not the case in patients with cancer. Likewise, for cancers in the body and tail of the pancreas it is necessary

to resect the spleen and its blood supply since it shares a blood supply with the tail of the pancreas. For benign diseases of the pancreatic tail, the spleen can be preserved.

There has been significant debate regarding the extent of lymph node dissection necessary in patients undergoing curative resection for pancreatic cancer. Table 52-5 shows the difference in extent of lymphadenectomy between the standard and radical procedure. The standard procedure includes the bile duct (station 12b2) and cystic duct lymph nodes (station 12c), the posterior (station 13) and anterior (station 17) pancreaticoduodenal lymph nodes, the SMV nodes (station 14v), and the nodes on the right side of the superior mesenteric artery (station 14b). Radical resection adds a distal gastrectomy (stations 3, 4, 5, and 6) and a retroperitoneal dissection extending from the right renal hilum to the left lateral border of the aorta horizontally with samples of celiac nodes, and from the portal vein to below the third portion of the duodenum vertically (lymph node stations 16a1, 16b2, and 9). In the United States, standard resection is most commonly performed.

Figure 52-10. A: Resectable pancreatic head cancer. There is a clear plane between the tumor and both the superior mesenteric artery and superior mesenteric vein. B: Borderline resectable pancreatic cancer. Involvement of the superior mesenteric vein with distortion and narrowing; tumor abutment of the superior mesenteric artery less than 80 degrees of the circumference.

Awareness of the common anatomic variants in biliary and pancreatic arterial supply is necessary to prevent major vascular injury and damage to the hepatic blood supply during pancreatic resection. The gastroduodenal artery is the largest named artery taken during pancreaticoduodenectomy. In the case of a replaced right hepatic artery arising from the superior mesenteric artery, the gastroduodenal artery can arise from this replaced vessel and enter the pancreas posterior to the bile duct. In addition, this replaced right hepatic artery courses to the liver lateral to the bile duct and can easily be injured during dissection of the pancreatic uncinate process off of the superior mesenteric vessels. A replaced right hepatic artery often supplies the entire right lobe of the liver causing significant hepatic ischemia if injured. In the case of a replaced right hepatic artery, there will still be a pulse medially in the hepatoduodenal ligament from the left hepatic artery, but this will supply only the left lobe of the liver.

In the case of a replaced common hepatic artery, the entire hepatic blood supply will be from the SMA. There will be no pulse medially in the hepatoduodenal ligament. The replaced vessel will again be posterior and lateral to the bile duct and at risk of injury if not correctly identified. Given the closer proximity of the replaced vessels to the pancreatic head and uncinate process, these replaced vessels may also be more prone to direct involvement by tumor. If injured or involved with tumor and resected, these often require reconstruction to restore adequate hepatic blood supply.

Due to the rich afferent sensory fiber network within the pancreas, abdominal pain and back pain are common presenting symptoms in patients with pancreatic cancer. As pancreatic cancer progresses, the nervous plexuses along the celiac axis in the retroperitoneum can be invaded by a tumor causing the characteristic intractable back pain. In this setting, celiac ganglion blockade (sympathectomy) or neurolysis using alcohol can provide significant pain relief by interrupting these somatic fibers. A celiac block can be performed endoscopically,⁵⁰ percutaneously, or intraoperatively. Endoscopic ultrasound (EUS)- or CT-guided celiac plexus neurolysis should be considered first-line therapy in patients with pain secondary to unresectable, locally advanced pancreatic cancer.⁵¹ Celiac blockade has been shown to reduce pain in patients with unresectable pancreatic cancer undergoing operative bypass procedures for obstructive jaundice and duodenal obstruction.^{52,53}

Pancreatic Anatomy and Pancreatitis

The intrapancreatic location of the distal common bile duct is critical to many pancreatic disease processes. Gallstone pancreatitis, the second most common cause of pancreatitis in the United States, is caused by gallstones passed into the common bile duct. These gallstones can obstruct the duct distally and lead to transient obstruction of the pancreatic duct with resulting reflux of pancreatic juice and bile into the pancreatic duct, causing pancreatitis.

In benign pancreatic diseases such as chronic pancreatitis, disease in the pancreatic head may cause benign biliary strictures and jaundice, whereas disease in the body and tail more often presents with abdominal pain. Pancreatic ductal anatomy and the presence or absence of ductal dilation dictate the choices for operative management. In the setting of a dilated pancreatic duct, drainage procedures may impact pancreatic pain and recurrent acute episodes. Conversely, in the setting of small duct disease, ablative therapy with resection (duodenum-preserving pancreatic head resection, pancreaticoduodenectomy, and distal pancreatectomy) is the treatment of choice when medical management fails.

Figure 52-11. Large pancreatic pseudocyst in the lesser sac. The pseudocyst is compressing the stomach anteriorly.

In the setting of acute or chronic pancreatitis, ductal disruption can lead to the formation of a pancreatic pseudocyst. In many cases, these pseudocysts occur anterior to the pancreas in the lesser sac (Fig. 52-11). This often leads to early satiety and abdominal pain. When large pseudocysts abut the stomach, drainage can be achieved with endoscopic or operative cystgastrostomy.

Trauma and Pancreatic Injury

The pancreatic body lies anterior to the second lumbar vertebra deep in the retroperitoneum. In cases of blunt abdominal trauma, specifically deceleration injury, the pancreatic body is crushed against the second vertebral body and can be transected at this point. In trauma patients with elevated amylase and lipase levels, the trauma surgeon should be aware of this possibility and obtain cross-sectional pancreatic imaging to rule out ductal disruption. In the case of complete ductal disruption distal pancreatectomy or drainage of the pancreas into the intestine may be necessary.

Penetrating injury to the duodenum or pancreas often involves major vascular injury and in many cases is not survivable. In the case of injury to the IVC, the pancreas and duodenum must be mobilized out of the retroperitoneum (Kocher maneuver) in order to expose the vessels.

DIAGNOSTIC APPROACH TO PATIENTS WITH PANCREATIC DISEASE

Pancreatic Imaging (Studies of Pancreatic Structure)

If pancreatic disease is suspected, the pancreas can be imaged by several radiographic modalities including plain abdominal x-rays, upper gastrointestinal series, abdominal ultrasonography, CT MRCP, endoscopic retrograde cholangiopancreatography (ERCP), and EUS.

Abdominal Plain Films

Plain films of the abdomen may be useful in patients with acute and chronic pancreatitis. In patients with acute pancreatitis, the most common finding on plain film include a generalized ileus with air fluid levels, a localized ileus or “sentinel loop” of jejunum or duodenum in the area of the inflamed pancreas,

or a cutoff of the colon due to distention of the transverse colon. In the setting of acute pancreatic fluid collections or pseudocysts, one may see an actual mass on plain film with displacement of the stomach or duodenum.²⁴ These findings are not sensitive or specific for acute pancreatitis, but in the setting of elevated amylase and lipase and associated abdominal symptoms can provide support for the diagnosis and an indication for more sensitive pancreatic imaging studies.

In the setting of chronic pancreatitis the most common finding on plain film is the presence of calcifications within the pancreas. These are most commonly seen at the level of the second lumbar vertebrae, where the pancreas lies in the retroperitoneum.

Upper Gastrointestinal Series

In the setting of a mass or mass effect on plain film, an upper gastrointestinal series can demonstrate displacement of the stomach or duodenum by a retroperitoneal mass. Displacement or narrowing of the duodenal C-loop suggests the presence of a pancreatic mass. However, the character of the mass (inflammatory, neoplastic, cystic, etc.) cannot be further defined on upper gastrointestinal series.²⁴ For this reason, upper gastrointestinal series has been largely replaced by ultrasound and other cross-sectional imaging modalities such as CT or MRCP.

Ultrasonography

Abdominal ultrasound can be useful in the setting of acute pancreatitis, chronic pancreatitis, pancreatic cystic lesions, pancreatic pseudocysts, and pancreatic cancer. In acute pancreatitis, the abdominal ultrasound may demonstrate gallstones, suggesting a potential etiology. In addition, the ultrasound can identify an enlarged pancreas, pancreatic edema and peripancreatic fluid collections consistent with the diagnosis of acute pancreatitis. Ultrasound can also identify pancreatic pseudocysts, cystic lesions, and other pancreatic masses.²⁴ Pancreatic pseudocysts usually appear as a smooth, round fluid collection without acoustic shadowing. A pancreatic cancer is more likely to distort the underlying pancreatic anatomy and appear as a localized, solid lesion on ultrasound, also without acoustic shadowing. Cystic neoplasms of the pancreas can have both solid and cystic components. They can be uniloculated or multiloculated and contain cysts of varying size. A large uniloculated neoplastic cyst is difficult to differentiate from a pancreatic pseudocyst.

Ultrasound examination can be limited by obesity, overlying bowel gas, recently performed barium contrast studies. Small masses or fluid collections can be easily missed. The presence of a mass on ultrasound is an indication for more extensive workup via CT or MRCP imaging.

Computed Tomography

Contrast enhanced, multidetector helical 3D CT is the most commonly performed study for the detection and characterization of pancreatic solid and cystic tumors. It is also useful in defining the pancreatic anatomy in the presence of chronic pancreatitis and identifying and following the complications of acute pancreatitis. CT is very sensitive for identifying pancreatic masses as small as 1 cm and can accurately distinguish solid from cystic lesions. The density of the lesion on CT can provide clues as to the diagnosis. Pancreatic adenocarcinomas are usually solid and hypodense, whereas pancreatic neuroendocrine tumors are vascular and appear hyperdense. Both pseudocysts and cystic lesions have components with fluid density.

CT is sensitive for the diagnosis of a malignant pancreatic adenocarcinoma. However, it is less sensitive and accurate in the diagnosis of cystic lesions. As CT scans are more commonly performed for a variety of indications, many cystic lesions are found incidentally. CT can be useful in identifying the characteristics associated with malignancy including tumor size greater than 3 cm, a dilated main pancreatic duct, and solid components within the cystic lesion.⁵⁴ However, significant controversy remains regarding observation versus resection of pancreatic cystic lesions.

Endoscopic Ultrasound

Compared to transabdominal ultrasound, EUS provides higher-resolution images of the pancreatic parenchyma and pancreatic duct. This procedure uses a transducer fixed to an endoscope that can be directed to the surface of the pancreas through the stomach or duodenum. EUS provides a useful adjunct to CT in the diagnosis of mucinous cystic lesions and malignancies. Pancreatic masses and cystic lesions can be well visualized on EUS, providing information about tumor size and invasion of major vascular structures. While more invasive than CT, EUS can provide useful additional information. EUS allows for fine-needle aspiration and/or biopsy, providing a tissue diagnosis, which is critical in the setting of

planned neoadjuvant therapy for pancreatic adenocarcinoma. EUS can also provide information about pancreatic ductal anatomy without the risk of invasive ERCP, which can cause severe pancreatitis.

A list of 11 EUS criteria has been defined for the diagnosis of chronic pancreatitis. The ductal criteria include pancreatic duct stones, echogenic ductal walls, irregular ductal walls, pancreatic duct strictures, visible side branches, and ductal dilatation. The parenchyma criteria include echogenic strands, echogenic foci, calcifications, lobular contour, and pancreatic cysts. Recent studies have determined that three or more EUS criteria provides the best balance of sensitivity and specificity for histologic pancreatic fibrosis.⁵⁵

Finally, in the setting of intractable pain in unresectable pancreatic cancer, chemical neurolysis of the celiac ganglion can be performed under EUS guidance. As with any endoscopic procedure, the risks include perforation of the stomach and/or duodenum.

Magnetic Resonance Cholangiopancreatography

MRCP is now being used more commonly as a noninvasive way to image both the biliary and pancreatic ducts. MRCP can provide excellent images and detect abnormalities of the common bile duct and main pancreatic duct, but it is more limited in its ability to detect abnormalities in the secondary ducts. This noninvasive imaging technique is very useful in high-risk patients and pregnant patients. It is also useful in diagnosis of persistent choledocholithiasis in the setting of gallstone pancreatitis. MRCP is most useful in settings where intervention such as biopsy or biliary drainage are unnecessary, thereby avoiding the risk of ERCP. MRCP can be a good modality for defining pancreatic ductal anatomy in patients with chronic pancreatitis and pancreatic pseudocysts to help plan operative management.

Endoscopic Retrograde Cholangiopancreatography

ERCP is the gold standard for providing information about pancreatic ductal anatomy. However, it is associated with significant complications and can often be avoided by using the previously described noninvasive tests. Five percent to 20% of patients develop clinical pancreatitis after ERCP and 25% to 75% have elevated amylase and lipase levels.²⁴ There is no way to prevent post-ERCP pancreatitis; however, high-pressure injection of the pancreatic duct is thought to contribute. Perforation of the gastrointestinal tract is a potential complication of ERCP.

ERCP is performed less commonly since much of the information can now be obtained with CT, MRCP, and/or EUS. However, it remains the procedure of choice when there is a high likelihood for the need of therapeutic intervention. For example, in patients with persistently elevated liver function tests in the setting of common duct stones ERCP is both diagnostic and therapeutic.

Pancreatic cancer is characterized by obstruction or stenosis of the pancreatic duct and or common bile duct (double-duct sign). ERCP remains the primary modality for palliation of obstructive jaundice with endostent placement. In chronic pancreatitis, the pancreatic duct may have irregularities including stenosis, dilation, sacculation, and ectasia. Pancreatic duct stones may be present within the pancreatic duct. Similar ductal changes can be observed immediately following acute attacks of pancreatitis. However, these abnormalities can be detected on MRCP or CT.

Chapter 53

Acute Pancreatitis

Jason S. Gold and Edward E. Whang

Key Points

- 1 In the United States, more than 75% of cases of acute pancreatitis are attributable to either gallstones or alcohol.
 - 2 In general, a diagnosis of acute pancreatitis can be made with the presence of two of the following three features: (1) characteristic abdominal pain (acute onset of severe, persistent epigastric pain often radiating to the back); (2) serum lipase (or amylase) levels at least three times greater than the upper limit of normal; and (3) findings of acute pancreatitis on contrast-enhanced CT or MRI.
 - 3 Approximately 80% of cases of acute pancreatitis are mild, associated with minimal systemic derangements, and generally resolve within 5 to 7 days, even with minimal therapy.
 - 4 Severe acute pancreatitis accounts for about 20% of cases and is defined as acute pancreatitis associated with one or more of the following: pancreatic necrosis, distant organ failure, and the development of local complications such as hemorrhage, abscess, or pseudocyst.
 - 5 The mortality rate associated with severe acute pancreatitis ranges from 10% to 20%, with half of the deaths in the first 2 weeks as the result of SIRS-induced multisystem organ failure and the remaining occurring later as the result of pancreatic necrosis/infection.
 - 6 The most important component of initial management of acute pancreatitis is fluid resuscitation.
 - 7 Early ERCP in acute pancreatitis has been subjected to extensive study. Early ERCP with stone extraction and sphincterotomy clearly benefits the subset of patients with gallstone pancreatitis who have cholangitis.
 - 8 Infection of pancreatic and peripancreatic necrosis complicates 30% to 70% of cases of acute necrotizing pancreatitis and most commonly becomes established during the second to third weeks after onset of disease.
 - 9 Infected necrosis is suggested by clinical signs such as persistent fever, increasing leukocytosis, and imaging findings such as gas in peripancreatic collections. When the necessary, infected necrosis can be confirmed by CT-guided fine needle aspiration.
 - 10 Invasive intervention is usually indicated in the presence of infected necrosis. In contrast, sterile necrotic collections almost never require intervention in the acute phase of necrotizing pancreatitis.
 - 11 Procedures for the treatment of infected necrosis are best performed when collections become walled off and demarcated from viable pancreatic tissue with at least partial liquefaction, which typically requires a delay of 4 to 6 weeks after disease onset.
 - 12 Drainage alone is now the initial recommended intervention for infected pancreatic necrosis. This is most often accomplished through a percutaneous image-guided approach. When percutaneous drains are placed, preference should be given to a retroperitoneal approach. Drainage can also be accomplished through an endoscopic transluminal approach.
 - 13 When required, débridement can often be performed through minimally invasive techniques.
 - 14 Current well-accepted indications for intervention on pseudocysts and walled-off necrosis in the absence of infection include the presence of symptoms attributable to the collection such as intractable pain or obstruction of the stomach, duodenum or bile duct.
 - 15 There are multiple treatment options available for the treatment of pancreatic pseudocysts and sterile walled-off necrosis, including percutaneous aspiration, percutaneous drainage, and internal drainage (performed transabdominally or endoscopically).
-

Acute pancreatitis is an acute inflammatory process of the pancreas with variable involvement of other regional tissues or remote organ systems.¹ In the United States, more than 250,000 patients are

hospitalized annually with acute pancreatitis as the primary diagnosis. It is the principal cause of approximately 3,000 deaths per year and a contributing factor in an additional 2,500 deaths. The direct cost attributable to acute pancreatitis exceeds \$2.5 billion per year in the United States.²

CLASSIFICATION AND DEFINITIONS

A useful system for defining and classifying acute pancreatitis and its complications was recently developed through an iterative process involving several national and international pancreas organizations.³ This new system is a modification of widely accepted but outdated classification system originally derived from a multidisciplinary symposium held in 1992.¹ The clinically based definitions reached by consensus are shown in [Table 53-1](#).

PATHOLOGY AND PATHOPHYSIOLOGY

The typical pathologic correlate of mild acute pancreatitis is *interstitial edematous pancreatitis*, in which the pancreatic parenchyma is edematous and infiltrated with inflammatory cells. Gross architectural features are preserved. In contrast, in *necrotizing pancreatitis* variable amounts of pancreatic parenchyma and peripancreatic fat have undergone tissue necrosis, with vascular inflammation and thrombosis being prominent features.

Studies using experimental models suggest that prototypical molecular and cellular derangements lead to pancreatic injury, regardless of the specific etiology or inciting event that triggers an episode of acute pancreatitis. Among the earliest of these derangements appears to be abnormal activation of proteolytic enzymes within pancreatic acinar cells.⁴ Under normal conditions, trypsinogen and other digestive zymogens are stored in granules that are segregated from lysosomal enzymes (e.g., cathepsin B) and acid. Early in the course of acute pancreatitis, cytoplasmic vacuoles containing activated proteolytic enzymes appear. How the digestive enzymes are activated, and what role these vacuoles play has been the subject of much investigation. In the prevailing model, trypsinogen is believed to be activated to yield trypsin either by colocalization with the lysosomal hydrolase cathepsin B⁵ or through autoactivation due to a moderately acidic pH⁶. It has been noted that the cytoplasmic vacuoles appearing in the acinar cell in experimental acute pancreatitis share expression of proteins with autophagosomes. Autophagosomes are vacuoles that degrade cellular components such as organelles in the process of autophagy. Highlighting the possible importance of autophagy in the development of pancreatitis, mice lacking expression of the autophagy-related gene *Atg5* in the pancreas fail to exhibit prototypical features of acute pancreatitis.⁷

CLASSIFICATION

Table 53-1 Terms Used in the Classification of Acute Pancreatitis

Term	Definition
Interstitial edematous pancreatitis	Acute inflammation and edema of the pancreas and peripancreatic tissues without necrosis
Necrotizing pancreatitis	Acute pancreatitis associated with necrosis of the pancreas or peripancreatic tissues
Acute peripancreatic fluid collection	Peripancreatic collection of simple fluid, not associated with an area of necrosis, occurring early in the course of acute pancreatitis and lacking a wall of granulation or fibrous tissue
Pseudocyst	Collection of fluid containing essentially no solid material enclosed by a wall of fibrous or granulation tissue, typically occurring more than 4 wks after onset of pancreatitis
Acute necrotic collection	A collection containing variable amounts of fluid and necrotic pancreas and/or peripancreatic tissue without a well formed encapsulating wall, typically occurring in the first 4 wks of an episode of necrotizing pancreatitis
Walled-off necrosis	An encapsulated collection of necrotic pancreas and/or peripancreatic tissue with variable amounts of fluid, usually occurring more than 4 wks after the onset of necrotizing pancreatitis

Figure 53-1. Schematic diagram depicting activation of proteolytic enzymes, possibly through colocalization of zymogen granules and lysosomes, and subsequent rupture of zymogen granules releasing the activated enzymes into the cytoplasm of the pancreatic acinar cell. The activated enzymes then undergo disordered basolateral discharge from the acinar cell into the pancreatic parenchyma.

Acinar cell injury induced by active trypsin allows it to be released into the pancreatic parenchyma (Fig. 53-1) where it activates more trypsin and other digestive enzymes (e.g., chymotrypsin, phospholipase, and elastase). Trypsin can also activate the complement, kallikrein-kinin, coagulation, and fibrinolysis cascades within the pancreatic parenchyma. Activation of these enzymes is believed to initiate a vicious cycle in which activated enzymes cause cellular injury, an event that leads to the release of even more destructive enzymes. This cycle can overwhelm defense mechanisms that normally serve to limit the injurious consequences of premature trypsin activation within the pancreas (e.g., pancreatic secretory trypsin inhibitor-mediated inhibition of trypsin activity).

An inflammatory response is then generated in response to the initial acinar cell injury. This inflammatory response is marked by the infiltration of the pancreatic parenchyma with immune cells such as neutrophils, macrophages, monocytes, and lymphocytes and the release of a broad range of proinflammatory mediators such as tumor necrosis factor (TNF) α ; interleukins (IL) 1 β , 6, and 8; platelet-activating factor; chemokines (i.e., CXCL2 and CCL2); prostaglandins; and leukotrienes. The inflammatory response, to a large extent, determines the severity of pancreatitis, and the blockade of several components of the inflammatory response ameliorates the disease and reduces mortality in experimental models. The understanding of how the initial acinar cell injury provokes an inflammatory response is incomplete, but it appears that reactive oxygen species (ROS) and innate molecular pattern

recognition (i.e., damage/danger-associated pattern molecules and toll-like receptors (TLRs) as well as the activation of transcription factors such as NF- κ B play a role.⁸

The result of these events is pancreatic autodigestion, with injury to the vascular endothelium, interstitium, and acinar cells. Increases in vascular permeability lead to interstitial edema. Vasoconstriction, thrombosis, and capillary stasis can lead to ischemic (and perhaps ischemia-reperfusion) injury and the development of pancreatic necrosis. With severe pancreatic injury, the systemic inflammatory response syndrome (SIRS) and distant organ failure can occur. The systemic complications are believed to be mediated by digestive enzymes and inflammatory mediators released from the injured pancreas. For example, activated phospholipase A-induced digestion of lecithin (an important component of pulmonary surfactant) may play a role in pathogenesis of acute respiratory distress syndrome (ARDS) that occurs in the setting of acute pancreatitis. In addition, the circulatory and inflammatory effects induced by acute pancreatitis are postulated to impair intestinal epithelial barrier function, allowing for the translocation of bacteria from the intestinal lumen into the systemic circulation. This phenomenon has been demonstrated to occur in animal models and may account for the pathogenesis of pancreatic and peripancreatic infection that can complicate necrotizing pancreatitis.

ETIOLOGY

1 Although many etiologies of acute pancreatitis have been described, in the United States, more than 75% of cases are attributable to either gallstones or alcohol.

Gallstones

Gallstones cause approximately 35% of episodes of acute pancreatitis in the United States. In a mechanistic model proposed over a century ago, a gallstone lodged at the papilla of Vater occludes the ampullary orifice, leading to retrograde reflux of bile into the pancreatic duct through a common channel shared by the common bile duct and the pancreatic duct (Fig. 53-2). Although elements of this model have been challenged, the prevailing view is that transient or persistent obstruction of the ampullary orifice by a gallstone or edema induced by stone passage is the inciting factor in the pathogenesis of gallstone-induced pancreatitis. *Microlithiasis* refers to aggregates (<5 mm in diameter) of cholesterol monohydrate crystals or calcium bilirubinate granules detected as “sludge” within the gallbladder on ultrasonography or on examination of bile obtained during endoscopic retrograde cholangiopancreatography (ERCP). An etiologic role for microlithiasis in acute pancreatitis remains unproved; however, data derived from case-control studies suggest that cholecystectomy or endoscopic sphincterotomy can reduce the risk of recurrent acute pancreatitis in patients with microlithiasis.

Figure 53-2. Illustration of the common channel concept. A gallstone lodged at the ampulla of Vater can cause reflux of bile into the pancreatic duct.

Alcohol

Ethanol causes approximately 40% of cases of acute pancreatitis in the United States. Most patients with alcohol-induced acute pancreatitis also have underlying chronic pancreatitis. Potential mechanisms by which alcohol-induced pancreatitis include sphincter of Oddi spasm, obstruction of small pancreatic ductules by proteinaceous plugs, alcohol-induced metabolic abnormalities (e.g., hyperlipidemia), and direct toxic effects induced by alcohol and its metabolites (e.g., acetaldehyde, acetate, and nonesterified fatty acids).

Other Etiologies

A wide range of other etiologies of acute pancreatitis have been identified (Table 53-2). Ongoing investigations are beginning to reveal specific gene abnormalities (e.g., mutations in cationic trypsinogen *PRSS1*, pancreatic secretory trypsin inhibitor *SPINK1*, and the cystic fibrosis transmembrane conductance regulator *CFTR*) that can be associated with pancreatitis. Patients for whom no etiology can be identified despite thorough evaluation are classified as having *idiopathic pancreatitis*.

ETIOLOGY

Table 53-2 Etiology of Acute Pancreatitis

Gallstones
Ethanol
Iatrogenic causes
ERCP
Abdominal and nonabdominal operations
Cardiopulmonary bypass
Trauma
Neoplasms (e.g., pancreatic cancer)
Pancreas divisum
Sphincter of Oddi spasm
Medications
Toxins
Parathion
Scorpion venom
Hyperlipidemia
Hypercalcemia
Infectious agents
Viruses (e.g., mumps and Coxsackie B viruses; HIV)
Bacteria (e.g., Salmonella and Shigella species; hemorrhagic Escherichia coli)
Biliary parasites (e.g., Ascaris lumbricoides)
Genetic causes
Cationic trypsinogen PRSS1 mutations
Pancreatic secretory trypsin inhibitor SPINK1 mutations
Cystic fibrosis transmembrane conductance regulator CFTR mutations
Autoimmune pancreatitis (lymphoplasmacytic sclerosing pancreatitis)
Vasculitis (e.g., systemic lupus erythematosus and polyarteritis nodosa)
Ischemia
Pregnancy
Endoscopic retrograde cholangiopancreatography (ERCP)

CLINICAL PRESENTATION

Abdominal pain, nausea, and vomiting are the most prevalent symptoms associated with acute pancreatitis. The pain is visceral in quality, is localized to the epigastrium, often radiates to the back, and may be alleviated with the patient leaning forward. Abdominal tenderness is the most prevalent sign of acute pancreatitis. Tachycardia and hypotension may result from intravascular hypovolemia. Low-grade fevers are common, but high-grade fevers are unusual in the absence of intra- or extrapancreatic infection. Jaundice may be evident in the presence of cholangitis (e.g., with gallstone-induced pancreatitis and persistent choledocholithiasis) or liver disease (alcohol-induced pancreatitis in a patient with cirrhosis). Evidence of retroperitoneal hemorrhage may become apparent if blood dissects into the subcutaneous tissues of the flanks (Grey Turner sign), umbilicus (Cullen sign), or

inguinal region (Fox sign); however, these findings are unusual. In approximately 20% of cases, acute pancreatitis is associated with SIRS, hemodynamic lability, and/or organ failure (particularly compromise of the cardiovascular, pulmonary, and renal systems) on presentation.

DIAGNOSIS

2 The differential diagnosis of acute pancreatitis includes other conditions causing acute upper abdominal pain, such as biliary colic and cholecystitis, acute mesenteric ischemia, small bowel obstruction, visceral perforation, and ruptured aortic aneurysm. Acute exacerbations of chronic pancreatitis can also be associated with clinical features resembling those of acute pancreatitis. In general, a diagnosis of acute pancreatitis can be made with the presence of two of the following three features: (1) characteristic abdominal pain (acute onset of severe, persistent epigastric pain often radiating to the back); (2) serum lipase (or amylase) levels at least three times greater than the upper limit of normal; and (3) findings of acute pancreatitis on contrast-enhanced computed tomography (CT) or magnetic resonance imaging (MRI).^{9,10} Imaging tests should be used selectively, to rule out other diagnoses and for the indications discussed later. In cases of typical abdominal pain and confirmatory laboratory tests, imaging is usually not needed at the time of admission.

Laboratory Tests

With pancreatic injury, a variety of digestive enzymes escape from acinar cells and enter the systemic circulation. Of these enzymes, amylase is the most widely assayed to confirm the diagnosis of acute pancreatitis. Amylase levels rise within several hours after onset of symptoms and typically remain elevated for 3 to 5 days during uncomplicated episodes of mild acute pancreatitis. Because of the short serum half-life of amylase (10 hours), levels can normalize as soon as 24 hours after disease onset. The sensitivity of this test depends on what threshold value is used to define a positive result (90% sensitivity with a threshold value just above the normal range vs. 60% sensitivity with a threshold value at three times the upper limit of normal). Specificity (which also varies with the threshold values selected) is limited because a wide range of disorders can cause elevations in serum amylase concentration. Assays that detect increases in the serum concentration of amylase of pancreatic origin (P-isoamylase) alone are associated with greater specificity. Increased urinary amylase concentrations and amylase-to-creatinine clearance ratios occur with acute pancreatitis; however, these parameters offer no advantage over serum amylase concentrations, except in the evaluation of macroamylasemia (in which urinary amylase excretion is not increased despite elevations in serum amylase concentration).

Serum lipase concentrations increase with kinetics similar to those of amylase. It has a longer serum half-life than amylase, however, and may be useful for diagnosing acute pancreatitis late in the course of an episode (at which time serum amylase concentrations may have already normalized). Although lipase is more specific than amylase in the diagnosis of acute pancreatitis, note that lipase is produced at a range of nonpancreatic sites, including the intestine, liver, biliary tract, and stomach, and tongue.

The magnitude of the increases in amylase or lipase concentrations has no correlation with severity of pancreatitis. In general, the magnitude of increases in amylase concentrations tends to be greater in patients with gallstone pancreatitis than in those with alcohol-induced pancreatitis; however, this finding is unreliable in distinguishing between these two etiologies.

Imaging Tests

Findings on plain radiographs associated with acute pancreatitis are nonspecific and include ileus that may be generalized or localized to a segment of small intestine (“sentinel loop”) or transverse colon (“colon cut-off sign”), psoas muscle margins that are obscured by retroperitoneal edema, an elevated hemidiaphragm, pleural effusions, and basilar atelectasis.

Ultrasonography may reveal a diffusely enlarged, hypoechoic pancreas. However, overlying bowel gas (particularly prominent with ileus) limits visualization of the pancreas in a large percentage of cases. Although ultrasonography has poor sensitivity in the diagnosis of acute pancreatitis, it plays an important role in the identification of the etiology of pancreatitis (e.g., the detection of gallstones).

CT scanning is the most important imaging test in the evaluation of acute pancreatitis. CT findings of mild acute pancreatitis include pancreatic enlargement and edema, effacement of the normal lobulated contour of the pancreas, and stranding of peripancreatic fat (Fig. 53-3). In addition, dynamic CT

scanning performed after the bolus administration of intravenous contrast can demonstrate regions of pancreas that have poor or no perfusion, as seen with pancreatic necrosis (Fig. 53-4). Detection of necrosis plays an important role in assessment of disease severity, as discussed further later. CT can also characterize collections and other complications associated with acute pancreatitis.

Figure 53-3. Computed tomography scan of acute interstitial pancreatitis.

Figure 53-4. Computed tomography scan of acute necrotizing pancreatitis.

MRI and magnetic resonance cholangiopancreatography (MRCP) are being used with increasing frequency in patients with acute pancreatitis. These examinations have the potential to offer better definition of pancreatic and biliary ductal abnormalities than CT scanning, and they are applicable in patients for whom ionizing radiation or iodinated intravenous contrast agents used in CT scanning are contraindicated. MRI can suggest the presence of pancreatic necrosis even without the use of intravenous gadolinium. MRI also has the advantage of better characterizing collections associated with acute pancreatitis, in particular with respect to differentiating solid from liquid components. Disadvantages of MRI include high cost, limited availability, and the long duration of examinations.

ASSESSMENT OF DISEASE SEVERITY

3 Approximately 80% of cases of acute pancreatitis are mild, associated with minimal systemic derangements, and generally resolve within 5 to 7 days, even with minimal therapy. The mortality rate associated with mild acute pancreatitis is less than 1%.

4, 5 Approximately 20% of cases are associated with either organ failure or the development of local complications. The mortality rate for these patients ranges from approximately 10% to 20% in contemporary series.¹¹⁻¹⁴ One-half of deaths occur within the first 2 weeks after the onset of symptoms; these deaths are primarily the result of SIRS-induced multisystem organ failure. Most of the remaining deaths occur beyond 2 weeks after presentation and result from complications of pancreatic necrosis, especially infection.

Accurate prediction of severity early in the course of disease offers potential benefits in that complications can be anticipated and detected early through the use of intensive monitoring and frequent clinical assessment, and early and aggressive therapies can be instituted to attempt to prevent these complications. Several methods for assessing disease severity based on clinical parameters, serum markers, imaging, and scoring systems have been widely studied.

Revised Atlanta and Determinant-Based Classifications

An optimal system for the classification of severity of acute pancreatitis has not been universally accepted. Nevertheless, it is widely recognized that organ failure and local complications, particularly necrosis, are the two most important predictors of disease severity. While these two variables are often associated, they differ as to when in the course of disease they typically arise and the manner in which they contribute to disease severity. The early phase of acute pancreatitis (generally the first week after onset of symptoms) is characterized by the host response to the local pancreatic injury. Disease severity in the early phase is thus determined by organ failure resulting from the systemic inflammatory response. Organ failure can be immediately apparent on clinical presentation, and in fact, organ failure occurring in the early phase of disease is usually present on admission. In contrast, pancreatic necrosis, which occurs in 5% to 10% of cases of acute pancreatitis, may not be apparent on initial presentation and the extent of local complications can continue to evolve into the late phase of disease. Organ failure and death in the late phase are often determined by local complications, particularly infected necrosis.³ While local complications can contribute to the mortality of patients with organ failure, there is also a subset of patients with pancreatic necrosis without organ failure who experience significant morbidity but have very low mortality.¹³

Two classification schemes based on organ failure and local complications have been proposed (Table 53-3).^{3,13,15} While these classification schemes are quite useful and validated in predicting mortality,^{11,14} their utility in predicting the course of disease on admission or within the first few days of hospitalization is limited by the fact that local complications and the resultant organ failure occurring in the late phase of the disease have not become apparent. Furthermore, a distinction is made between transient organ failure and persistent organ failure. This distinction cannot be made at the time of presentation. Similarly, the distinction between sterile necrosis and infected necrosis in the Determinant-Based Classification cannot be made with certainty until a patient with necrotizing pancreatitis shows signs of resolution.

Scoring Systems

The Ranson criteria, which is based on age, white blood cell count (WBC), glucose, serum lactate dehydrogenase (LDH), and serum aspartate aminotransferase (AST) all determined on admission as well as hematocrit drop, blood urea nitrogen (BUN), serum calcium, arterial partial pressure of oxygen (PaO₂), base deficit, and fluid requirement all determined after 48 hours, are easily tabulated, and the resulting scores are well correlated with morbidity and mortality rates.¹⁶ The presence of three or more of these criteria is indicative of severe acute pancreatitis. Important limitations of the Ranson criteria are that the predictive score cannot be determined prior to 48 hours following admission and that it can only be used once. Furthermore, because these criteria were developed using a cohort of patients for whom alcohol was the predominant etiology of pancreatitis, their generalizability may be limited. A similar predictive scoring system developed in Glasgow using a cohort of patients for whom gallstones were the predominant etiology of pancreatitis is available.¹⁷

Acute Physiology and Chronic Health Evaluation (APACHE) II scores, which are based on patient age, indices of chronic health, and physiologic parameters, can be determined at any time after admission, can be updated continuously during the course of disease and may have greater predictive power than Ranson scores.¹⁸ However, the complexity of calculating APACHE II (or related APACHE III) scores limits its application in routine clinical practice.

STAGING

Table 53-3 Criteria for Assessing Severity of Pancreatitis

Revised Atlanta Classification ³
Mild acute pancreatitis
■ No organ failure AND
■ No local or systemic complications
Moderately severe acute pancreatitis
■ Transient organ failure without persistent organ failure AND/OR
■ Local or systemic complications
Severe acute pancreatitis
■ Persistent organ failure
■ Organ failure defined by cardiovascular failure (systolic blood pressure, <90 mm Hg and not fluid responsive), respiratory failure ($\text{PaO}_2/\text{FiO}_2 \leq 300$), or renal failure (serum creatinine ≥ 1.9 mg/dL)
■ Transient organ failure resolves in <48 hrs, persistent organ failure lasts >48 hrs
■ Local complications include peripancreatic fluid collections and acute necrotic collections
■ Systemic complications are exacerbations of underlying comorbidities related to the acute pancreatitis
Determinant-Based Classification ^{13,15}
Mild acute pancreatitis
■ No (peri)pancreatic necrosis AND
■ No organ failure
Moderate acute pancreatitis
■ Sterile (peri)pancreatic necrosis AND/OR
■ Transient organ failure
Severe acute pancreatitis
■ Infected (peri)pancreatic necrosis OR
■ Persistent organ failure
Critical acute pancreatitis
■ Infected (peri)pancreatic necrosis AND
■ Persistent organ failure
■ Organ failure defined by cardiovascular failure (need for inotropic agent), respiratory failure ($\text{PaO}_2/\text{FiO}_2 \leq 300$ mm Hg), or renal failure (creatinine ≥ 2.0 mg/dL)
■ Transient organ failure resolves in <48 hrs, persistent organ failure lasts ≥ 48 hrs

Recently another scoring system, the Bedside Index for Severity in Acute Pancreatitis (BISAP), based on five relatively straightforward parameters that are obtained within the first 24 hours of hospital admission, has been proposed. One point is assigned for the presence of each of the following: BUN > 25 mg/dL, impaired mental status, SIRS, age > 60 years, and the presence of a pleural effusion.¹⁹ The BISAP has been validated and is comparable to the Ranson criteria^{20,21} and the APACHE II Score^{19,21,22} in its prediction of mortality.

Computed Tomography Scanning

The diagnostic application of CT scanning was discussed previously. Although not required for making a diagnosis on admission, a CT is often useful in patients who deteriorate or fail to improve. This technique is associated with greater than 90% sensitivity in the detection of pancreatic necrosis, a finding that is predictive of disease severity. Furthermore, CT scanning can also diagnose and characterize collections and can indicate infection (e.g., if air bubbles are present) in some cases. Because necrosis takes time to develop (in some patients up to 5 days), a contrast-enhanced CT scan obtained too early in the disease course (e.g., at the time of admission) does not have predictive value beyond clinical assessment (i.e., APACHE II or BISAP scoring).²³ In addition, concerns that early administration of iodinated intravenous contrast agents used in CT scanning may exacerbate pancreatic injury have been raised, although these agents have not been shown to cause or exacerbate pancreatitis in humans.²⁴

Serum and Urinary Markers

C-reactive protein (CRP) is an easily assayed marker for which serum concentrations are well correlated with disease severity. However, CRP levels do not become significantly elevated until 48 hours after onset of disease; therefore, this marker is not useful for early prediction of disease severity. Lipopolysaccharide-binding protein (LBP), a class 1 acute-phase protein that binds and transfers bacterial lipopolysaccharide (LPS), has also been shown to correlate with disease severity but its elevation is similarly delayed. Serum concentrations of IL-6, IL-8, neutrophil elastase, angiopoietin-2, procalcitonin, and urinary concentrations of TAP (a product of trypsinogen activation) are also correlated with disease severity. Because these markers become elevated within 24 hours of disease

onset, they may be relevant to early prediction strategies in the future. Currently, however, assays for these markers are not widely available.

MANAGEMENT

The goals of management for patients with acute pancreatitis are summarized below.

Correcting Pathophysiologic Derangements and Ameliorating Symptoms

6 The most important component of initial management is fluid resuscitation. In severe pancreatitis, third-space fluid losses can be large, with up to one-third of plasma volume being sequestered. The failure to appropriately resuscitate these patients is associated with increased morbidity and mortality. An indwelling urinary catheter should be placed, intravascular volume should be frequently assessed, and aggressive fluid and electrolyte replacement should be ensured. It should be noted, however, that adverse consequence of massive resuscitation can also complicate the course of patients with severe pancreatitis, and some recent studies have suggested an association between overresuscitation and increased complications and death. While the optimal fluid resuscitation strategy is not known, critically ill patients with pancreatitis should likely be aggressively and promptly resuscitated with lactated Ringer solution with the amount of fluid administered tailored individually based on signs of end-organ perfusion such as stabilization of blood pressure and heart rate and production of adequate urine output.^{9,10,25}

Patients with potentially severe pancreatitis, as well as those for whom initial resuscitation fails, are best managed in a dedicated intensive care unit (ICU). Central venous monitoring may facilitate fluid management. Patients should be closely monitored for development of distant organ failure, particularly respiratory, cardiovascular, and renal failure, so that supportive management of these conditions (positive-pressure ventilation, administration of vasopressor agents, and hemodialysis, respectively) can be instituted without delay.

Abdominal pain is usually ameliorated with intravenous narcotics. In the past, morphine was avoided because of concerns that morphine-induced increases in sphincter of Oddi pressure might exacerbate an episode of pancreatitis. However, there is no clinical evidence that morphine can induce or exacerbate acute pancreatitis. Other analgesic agents commonly used in patients with acute pancreatitis include meperidine and fentanyl. Evacuation of gastric contents using a nasogastric tube should be instituted if vomiting is a prominent symptom; otherwise, it is unnecessary.

A fraction of patients with severe pancreatitis develop abdominal compartment syndrome (ACS). ACS is defined as a life-threatening sustained elevation of intra-abdominal pressure associated with new-onset organ failure or acute worsening of existing organ failure. ACS usually manifests with a tensely dilated abdomen, oliguria, and increased peak airway pressures. The diagnosis and treatment of ACS is discussed in more detail elsewhere in this book. In acute pancreatitis, ACS is associated with very severe disease, and approximately half of patients with ACS do not survive. ACS is treated by attempting to decrease intra-abdominal pressure. In some patients this can be accomplished by draining intra-abdominal collections and/or decompressing the bowel with nasogastric and rectal tubes. More than half of the patients with ACS in the setting of acute pancreatitis require a decompressive laparotomy.^{9,26}

Minimizing Progression of Pancreatic Inflammation and Injury

Identification of strategies for interrupting the inflammatory cascades that induce pancreatic injury and distant organ failure is an area of active investigation. Currently, the only method used in routine clinical practice is bowel rest (nothing by mouth). The rationale underlying this approach is that avoidance of bolus oral nutrient intake may limit stimulation of pancreatic exocrine secretion induced by the presence of nutrients in the intestine, particularly the duodenum.

Patients with mild acute pancreatitis generally need no nutritional support, as their disease typically resolves within 1 week. In contrast, patients with severe pancreatitis usually have a more prolonged disease course and should begin to receive nutritional support as early as feasible. Although these patients traditionally have been administered total parenteral nutrition (TPN), accumulating evidence suggests that enteral nutrition is safe, is less costly, and may be associated with a lower complication rate than TPN.²⁷ Administration of enteral nutrition is also associated with the theoretical advantage of helping to maintain the integrity of the intestinal mucosal barrier, thus potentially limiting or preventing bacterial translocation. Enteral nutrients have typically been delivered to the jejunum

through nasojejunal tubes to avoid stimulating pancreatic exocrine secretion, however, randomized controlled trials indicate that continuous feedings delivered through nasogastric tubes are equally safe and effective.^{28,29} TPN is still required in many patients who do not tolerate enteral nutrition due to ileus.

Clinical trials of agents that inhibit activated pancreatic enzymes, inhibit pancreatic secretion, or interrupt the inflammatory cascade have yielded disappointing results. Meta-analyses of clinical trials of gabexate mesylate (a proteinase inhibitor), somatostatin, and octreotide suggest these agents have limited, if any, efficacy in improving outcomes in acute pancreatitis. A platelet-activating factor antagonist, lexipafant, showed promise in an initial study but not in a subsequent larger trial and is not currently recommended. Other adjuncts for which clinical trials have failed to demonstrate efficacy in limiting pancreatic injury in patients with acute pancreatitis include glucagon, anticholinergics, fresh frozen plasma, and peritoneal lavage.

Treating the Underlying Cause

7 This discussion is particularly relevant to patients with gallstone pancreatitis. There are both theoretical and experimental rationales to believe that removal of gallstones impacted at the ampulla of Vater early in the course of an episode of acute gallstone pancreatitis might limit disease severity. On the other hand, most gallstones that cause acute pancreatitis readily pass into the small intestine. The benefit of early ERCP in acute pancreatitis has been subjected to extensive study.³⁰ It has been shown that early ERCP with stone extraction and sphincterotomy clearly benefits the subset of patients with gallstone pancreatitis who have cholangitis. There also may be a benefit in patients with biliary obstruction who do not have cholangitis, although this is less clear. In patients, with cholangitis, ERCP should be performed urgently (within 24 hours). The timing of ERCP in patients with biliary obstruction is not clear (24 to 72 hours). It is reasonable to wait up to 48 hours for biliary obstruction to resolve. MRCP and endoscopic ultrasound (EUS) may be reasonable to screen for persistent choledocholithiasis in equivocal cases to prevent unnecessary intervention. In the absence of obstructive jaundice and/or cholangitis, early ERCP is associated with high complication rates but no apparent benefits and is therefore not recommended.

There is an approximately 18% incidence of recurrent pancreatitis or other gallstone-related complications during the 6-week period following an episode of gallstone pancreatitis in patients who do not undergo cholecystectomy.³¹ Indeed, there is a substantial incidence of recurrent pancreatitis and gallstone-related complications in patients with biliary pancreatitis whose cholecystectomy is delayed even 2 weeks after hospital discharge.³² Therefore, cholecystectomy should be performed during the same hospitalization for most patients with mild gallstone pancreatitis. This strategy does not increase operative complications, conversion to open procedures, or mortality.³¹ In severe biliary pancreatitis, the risk of deferring surgery needs to be balanced against the risk of performing early surgery in patients who are debilitated and nutritionally compromised. Endoscopic sphincterotomy is another option, however, the high risk of recurrent gallstone-related complications and the higher mortality compared to cholecystectomy suggest that this strategy should be reserved for patients with severe comorbidities precluding safe surgery.^{31,33}

Examples of other measures directed at correcting the underlying cause of pancreatitis include cessation of drugs known to cause pancreatitis and treatment of hypercalcemia or hyperlipidemia.

Preventing and Treating Complications

Complications of acute pancreatitis include pancreatic abscesses and infected necrosis, pseudocysts and walled-off necrosis, pancreatic ascites and fistulas, splenic vein thrombosis, and arterial pseudoaneurysms (Table 53-4). Infected necrosis as well as pseudocysts and sterile walled-off necrosis are discussed in detail below.

Infected Necrosis

8, 9 Infection of pancreatic and peripancreatic necrosis complicates 30% to 70% of cases of acute necrotizing pancreatitis and most commonly becomes established during the second to third weeks after onset of disease. Historical data suggest that mortality rates associated with untreated infected necrosis approach 100%. Infected necrosis is suggested by clinical signs such as persistent fever, increasing leukocytosis, and imaging findings such as gas in peripancreatic collections. When necessary, infected necrosis can be confirmed by cultures of aspirates of fluid or necrotic tissue obtained during CT-guided fine needle aspiration (FNA) or specimens collected during surgery. The concordance rate between

bacteriologic results of FNA and those of surgical specimens is greater than 95%.³⁴ The peak occurrence of infected necrosis is between 2 and 4 weeks after presentation but it may occur at any time during the clinical course.

COMPLICATIONS

Table 53-4 Local Complications of Acute Pancreatitis

Necrosis
Infected necrosis
Pancreatic pseudocyst
Pancreatic ascites
Enteric or colonic fistula
Splenic vein thrombosis
Arterial pseudoaneurysm
Hemorrhage
Abdominal compartment syndrome

10 Invasive intervention is usually indicated in the presence of infected necrosis. In contrast, sterile necrotic collections almost never require intervention in the acute phase of necrotizing pancreatitis. As infected necrosis often consists of thick and tenacious materials, traditionally mechanical débridement via an open surgical approach was the primary treatment. Recently, less invasive approaches have been popularized. Minimally invasive approaches for the treatment of infected pancreatic necrosis are associated with fewer complications, however the mortality rate and the length of hospital stay appear to be predominantly determined by the disease process itself rather than the interventional approach. In centers with the appropriate expertise, most cases of infected pancreatic necrosis can now be managed using minimally invasive techniques.

11 Procedures for the treatment of infected necrosis are best performed when collections become walled-off and demarcated from viable pancreatic tissue with at least partial liquefaction, which typically requires a delay of 4 to 6 weeks after disease onset. This is especially true for débridement, as when it is performed too early, bleeding, incomplete removal of infected necrosis, resection of vital tissue, and loss of endocrine and exocrine function are more likely to ensue. Convincing evidence now supports delaying intervention whenever possible. Antibiotics can often be used to temporize the situation allowing necrotic collections to mature. A subset of patients may even be successfully treated with antibiotics alone. Patients with clinical deterioration and signs of sepsis despite the use of antibiotics who have clearly infected acute necrotic collections may require intervention within the first few weeks of acute pancreatitis.^{9,10,35}

12 Drainage alone is the initial recommended intervention for infected pancreatic necrosis. This is most often accomplished through a percutaneous image-guided approach, which is technically feasible in the vast majority of cases. When percutaneous drains are placed, preference should be given to a retroperitoneal approach so that the drain tract can be used to perform video-assisted retroperitoneal débridement (VARD, see below). Drainage can also be accomplished through an endoscopic transluminal approach, particularly in the rare cases where a percutaneous approach is not feasible. Drainage alone can successfully treat infected necrosis in approximately 1/3 to 1/2 of cases.^{9,10,35–38}

13 When required, débridement can often be performed through minimally invasive techniques. These techniques are reserved for patients without intra-abdominal catastrophes or other complications of acute pancreatitis mandating surgical exploration. VARD and direct endoscopic necrosectomy (DEN) are the two most widely utilized techniques for minimally invasive débridement.

VARD is usually accomplished through a retroperitoneal approach via flank incisions. The previously placed drain tracts are dilated to insert an operative nephroscope over a wire or to place laparoscopic ports that follow the drain tract into the retroperitoneum. Fluid that is encountered is suctioned and submitted for culture. Hydrodissection is used liberally. Gentle débridement of solid debris can be accomplished under direct vision through the entry site or under visualization with the videoscope. The goal of VARD is to facilitate drainage and not necessarily to perform a complete necrosectomy. Irrigation is usually continued postoperatively through surgically placed drains. In a multicenter randomized controlled trial, patients with infected pancreatic necrosis were randomized to undergo primary open necrosectomy or a step-up approach consisting of percutaneous or endoscopic drainage followed, in most cases (65%), by VARD. Open necrosectomy was rarely used when VARD could not be

accomplished. Although mortality between the two groups did not differ, primary open necrosectomy was associated with a higher incidence of major complications and increased cost.³⁹

DEN is performed via transmural puncture into a necrotic collection after insertion of an endoscopic. It is required that the collection abuts or is in close proximity to the stomach or duodenum. The collection can be visualized as a bulge in the wall of the viscera or using EUS. The tract into the collection is then dilated and large bore stents are placed. Mechanical débridement can be performed with endoscopic instruments and/or irrigation. Nasocystic or percutaneous drains can be used to provide irrigation after the procedure. Typically, multiple sessions are necessary to completely débride the cavity. A small randomized controlled trial showed a decreased inflammatory response as well as decreased complications for patients undergoing endoscopic transgastric necrosectomy as opposed to VARD after failure of drainage for infected pancreatic necrosis.

Open necrosectomy may still be performed in the subset of patients not amenable to a minimally invasive approach or in centers without expertise in these techniques. For open necrosectomy, the abdomen is usually entered through a vertical midline or bilateral subcostal incision. The anterior surface of the pancreas can be exposed by dividing the gastocolic ligament (greater omentum) and entering the lesser sac. If inflammatory changes have obliterated the lesser sac, an alternative route to the pancreas is achieved by dividing avascular portions of the transverse mesocolon. Clearly nonviable tissue should be débrided bluntly without attempting to perform anatomic resections. The débridement field is irrigated with several liters of sterile saline. There are several options for assuring that all necrotic tissue is removed after surgery. Traditionally, when the abdomen is closed, large-bore drains are placed, and postoperatively the drains are left in place at least 7 days and until the effluent becomes clear. This procedure is known as *necrosectomy with closed drainage*. Several authors prefer variants of this procedure in which either both gauze packing and drains are placed at the time of surgery and gradually withdrawn postoperatively (*necrosectomy with closed packing*) or where high-volume lavage of the lesser sac is performed through the drains placed at the time of surgery until the effluent becomes clear and the patient's clinical course improves (*necrosectomy with continuous lavage*). Other procedures including *necrosectomy with open packing*, where the retroperitoneum is marsupialized and the abdomen left open, and *necrosectomy with planned, staged relaparotomy*, in which the initial operation is followed by repeat laparotomies to change gauze packing or to perform additional débridement have fallen out of favor but may be necessary if necrosectomy is performed early in the course of disease before clear demarcation between necrotic and viable tissues has occurred. Modern mortality rates associated with necrosectomy performed for infected necrosis range from 10% to 20%.^{40,41} On long-term follow-up, approximately 25% of survivors develop exocrine insufficiency, and 30% develop endocrine insufficiency. It should be noted that open necrosectomy is associated with better results in more recent series due to improvements in ICU care and implementation of delayed timing for surgery. The results of open necrosectomy in relation to VARD or DEN have not been directly compared after initial drainage. Although surgical débridement is clearly indicated for infected necrosis, its role in sterile necrosis has undergone evolution. In the past, early necrosectomy was recommended for patients with necrotizing pancreatitis, even in the absence of documented infection. The rationale for this approach was to prevent infection from developing and to remove the source of toxins and inflammatory mediators. Today, it is recommended that surgery should be avoided in patients without documentation of infected necrosis, based on favorable outcomes reported using this conservative approach.^{40,41} However, there remains a subset of patients with sterile necrosis who, despite prolonged supportive care, have persistent problems, including disabling pain, malaise, and gastric outlet obstruction who may benefit from interventions for sterile necrosis late in the course of disease.

Because of the high morbidity and mortality rates associated with infected necrosis, there has been much investigation into the use of antibiotics as prophylaxis against infection. Initial clinical trials failed to demonstrate a benefit of prophylactic antibiotics; however, these studies were flawed by the inclusion of patients with mild disease who were at low risk for developing infected necrosis and the use of antibiotics with poor penetration into the pancreas. Trials were published in the 1990s showing a significant reduction in the incidence of pancreatic infection among patients receiving antibiotic prophylaxis, and based on this evidence, the use of antibiotic prophylaxis in patients documented to have necrotizing pancreatitis has become a widespread practice. Several recent trials that failed to show a benefit for prophylactic antibiotics have now been published.^{42,43} Similarly, recent meta-analyses of the available trials have failed to demonstrate a benefit for patients receiving prophylactic antibiotics.^{44,45} Disadvantages of using prophylactic antibiotics include the risks of fungal superinfection and the selection of resistant organisms. Another strategy for prophylaxis against infection in patients

with acute pancreatitis has been the administration of probiotic bacteria to reduce the load of pathogenic bacteria in the bowel; however, prospective evaluation has yielded disappointing results.⁴⁶

An algorithm for the general management of acute pancreatitis and pancreatic necrosis is shown in Algorithm 53-1.

Algorithm 53-1. Algorithm for the management of acute pancreatitis.

Pseudocysts and Sterile Walled-Off Necrosis

Acute fluid collections develop in up to 30% to 50% of patients with acute pancreatitis. As most resolve spontaneously, no specific treatment directed at acute fluid collections is necessary in the absence of evidence that the fluid is infected. However, in up to 10% of patients with acute pancreatitis, these fluid collections progress to develop a wall of fibrous granulation tissue. Until recently, predominantly liquid collections with a well-formed wall appearing after an episode of acute pancreatitis were classified as *pseudocysts*. It is now appreciated that many of the chronic collections seen after bouts of acute pancreatitis contain variable amounts of solid materials from the necrosis of pancreatic and peripancreatic tissues. In the new taxonomy, these collections are called walled-off necrosis. This distinction may better indicate how these collections should be treated, however, there is no distinction in the indication for intervention between pseudocysts and sterile walled-off necrosis.³⁵ The walls of these collections generally require at least 4 weeks from the onset of pancreatitis to mature. In contrast to true cysts, pseudocysts (and walled-off necrosis) do not have epithelium-lined walls.

Most pseudocysts and sterile walled-off necrosis are asymptomatic; however, they can cause upper abdominal pain, gastric outlet obstruction, and obstructive jaundice. Pseudocysts and walled-off necrosis can be diagnosed on ultrasonography or CT scanning (Figs. 53-5 and 53-6). It is important to distinguish

cystic neoplasms of the pancreas from these lesions, as cystic neoplasms can be malignant or have malignant potential. Cystic lesions of the pancreas are being diagnosed with increasing frequency due to the routine use of CT and MRI scans. Cystic neoplasms of the pancreas can usually be differentiated from pseudocysts and walled-off necrosis by the lack of evidence for antecedent pancreatitis or pancreatic trauma, or by the appearance on imaging studies. Pseudocysts are typically round, unilocular, and have a dense wall. In contrast, walled-off necrosis is typically heterogeneous with liquid and nonliquid density, with varying degrees of loculations, and is encapsulated by a well-defined wall. FNA, either by an image-guided percutaneous approach or an EUS-guided approach, can be used in cases where it is difficult to differentiate between pseudocysts or walled-off necrosis and cystic neoplasms. Pseudocysts and walled-off necrosis usually contain fluid with high amylase concentrations. In contrast, most neoplastic cysts do not communicate with the pancreatic duct and contain fluid with low amylase concentrations. These criteria, however, lack absolute predictive power.

Figure 53-5. Computed tomography scan of pancreatic pseudocyst.

Figure 53-6. Computed tomography scan of walled-off necrosis. *Arrows* indicate the presence of solid material within the collection.

14 The management of pseudocysts and walled-off necrosis continues to evolve. In the past, surgical drainage of pseudocysts was recommended for all pseudocysts (even if asymptomatic) that persisted beyond a 6-week period of observation. This recommendation was based on a widely quoted report which suggested that pseudocysts that persist more than 6 weeks rarely resolve spontaneously and are associated with high complication rates.⁴⁷ However, subsequent reports suggest that the natural history of asymptomatic pseudocysts follows a more benign course, with most pseudocysts less than 6 cm in diameter resolving spontaneously without complications.^{48,49} Even large, persistent collections may never cause symptoms or complications. Current well-accepted indications for intervention in the absence of infection include the presence of symptoms attributable to the collection such as intractable pain or obstruction of the stomach, duodenum, or bile duct.^{9,10,35,50}

15 There are multiple treatment options available for the treatment of pancreatic pseudocysts and sterile walled-off necrosis, including percutaneous aspiration, percutaneous drainage, and internal drainage (performed transabdominally or endoscopically). The optimal indications for these procedures

are not conclusively determined. Percutaneous aspiration alone is associated with high recurrence rates. Patients with chronic pancreatitis or pancreatic ductal abnormalities, particularly severe strictures or discontinuity of the pancreatic duct, have a high rate of failure with percutaneous drainage of pseudocysts. Percutaneous drainage alone should be avoided in these circumstances but may have a high rate of success in patients with normal ducts.⁵¹ Endoscopic cystgastrostomy is an option for patients in whom the pseudocyst or walled-off necrosis is intimately adherent to the stomach or duodenum. This procedure is accomplished by transmural puncture of the pseudocyst, balloon dilation of the tract, and placement of a stent connecting the pseudocyst to the stomach. A small, single-center randomized controlled trial of surgical cystgastrostomy versus endoscopic cystgastrostomy (along with ERCP and stenting of pancreatic duct leaks or strictures) for pseudocysts showed equal efficacy along with decreased hospital stay and cost for the endoscopic arm.⁵² The treatment of symptomatic sterile walled-off necrosis can also be accomplished endoscopically (see description of DEN above). Due to the presence of necrotic debris within these collections, in contrast to pseudocysts, the need for multiple stents and/or multiple procedures, often with mechanical débridement, should be expected when walled-off necrosis is approached endoscopically. As of yet, high-quality data comparing the efficacy of surgical versus endoscopic treatment of symptomatic, sterile walled-off necrosis are lacking.

The most commonly performed surgical procedures used to treat pseudocysts and sterile walled-off necrosis include cystgastrostomy, cystoduodenostomy, and Roux-en-Y cystojejunostomy. Cystgastrostomy or cystoduodenostomy is applicable if a portion of the pseudocyst wall is adherent to the stomach or duodenum respectively allowing for the creation of an anastomosis. Otherwise, the cyst wall can be anastomosed to a Roux limb of jejunum. These procedures, which can be performed as open or laparoscopic operations, should be delayed until pseudocyst wall maturation occurs. Mortality rates associated with surgical drainage procedures average less than 5%, with pseudocyst recurrence rates averaging 10%.

Chapter 54

Chronic Pancreatitis

Katherine A. Morgan and David B. Adams

Key Points

- 1 Chronic pancreatitis is heterogeneous in etiology with an increasingly recognized role of smoking and genetic factors.
 - 2 The most common indication for intervention in chronic pancreatitis is severe, debilitating abdominal pain.
 - 3 Medical and endoscopic therapies are frontline management of chronic pancreatitis, but are often unsuccessful.
 - 4 Surgical intervention is aimed at achieving durable pain relief with least perioperative and long term morbidity.
 - 5 Cutting edge therapies for chronic pancreatitis include total pancreatectomy with islet autotransplantation and minimally invasive techniques (laparoscopic and robotic).
-

INTRODUCTION

Chronic pancreatitis (CP) is an inflammatory disorder of the pancreas marked by fibrotic replacement of the pancreatic parenchyma. The clinical hallmark of disease is severe, debilitating, and recalcitrant abdominal pain, often associated with nutritional failure. CP typically results in progressive endocrine failure (type 3c diabetes mellitus)¹ and exocrine failure (malabsorption) in afflicted patients. Management of this challenging disorder is problematic due the complexities of disease pathogenesis, the clinical management of pain, and attendant impairments in patient quality of life.

EPIDEMIOLOGY

CP is a significant public health concern. Its prevalence and annual incidence are estimated at 0.2% to 0.6% and 7 to 10/100,000 respectively in the United States and Europe.² The economic impact is notable, with estimated annual healthcare expenditures for pancreatitis in the United States in 2004 were \$3.7 billion.³

ETIOLOGY

The etiology of CP is heterogeneous and multifactorial. The M-ANNHEIM classification can be utilized to describe the (M) multiple risk factors for the development of pancreatitis including (A) alcohol consumption, (N) nicotine use, (N) nutrition, (H) hereditary factors, (E) efferent ductal obstruction, (I) immunologic factors, and (M) metabolic factors.⁴

Historically, alcohol use has been the most commonly implicated etiologic factor in CP in the Western world, classically comprising 60% to 90% of cases in observational studies in the 1970s to the 1990s.^{5–7} More recent data from multiinstitutional prospective data, however, have demonstrated a lesser contributory role from alcohol, with association in approximately 45% of cases.⁸ Dose and duration of alcohol consumption have been demonstrated to be contributory to CP development, although several more recent studies suggest that alcohol alone is not sufficient to cause CP. Byproducts from ethanol metabolism injure acinar cells and can activate pancreatic stellate cells (PSCs) to form extracellular matrix. Recent investigation suggests an association between pancreatitis and a locus on the X chromosome. A risk factor for alcoholic pancreatitis on the X chromosome may partially explain the higher incidence of alcoholic pancreatitis in men than in women, a difference that cannot be explained

solely by alcohol consumption rate differences in men and women. In women, the high-risk allele acts as a recessive genetic disorder with consequent risk diminishment.⁹

1 Smoking has been determined as a significant risk factor in the development of CP. In the 1990s, a relationship between tobacco consumption and pancreatic calcifications was noted.¹⁰ In addition, the synergistic effects of smoking and alcohol have been described.¹¹ More recently, a large multicenter epidemiologic study has shown that smoking is an independent risk factor for CP in a dose-dependent fashion.^{8,12} In addition, tobacco use has been shown to be a strong risk factor for the progression of acute pancreatitis to CP, suggesting a role for smoking in pancreatic fibrogenesis.¹³

Genetic causes of CP have been increasingly recognized over the past couple of decades. In 1952, Comfort and Steinberg¹⁴ described hereditary pancreatitis (HP) and in 1996, Whitcomb and colleagues delineated a mutation in the cationic trypsinogen gene PRSS1, which results in the inappropriate activation of trypsin and is responsible for HP.¹⁵ HP is an autosomal dominant disorder with 80% penetrance, marked by recurrent acute pancreatitis beginning in early childhood, progression to CP in many, and a greatly (50×) increased risk of pancreatic cancer beginning in the fifth decade. Since, several other mutations in the PRSS1 gene have been identified. In addition, multiple other genetic foci have been implicated as contributing agents in CP as well, primarily related to the inappropriate activation of trypsin. Pancreas secretory trypsin inhibitor (serine protease inhibitor, kazal type 1, and SPINK1),¹⁶ cystic fibrosis transmembrane conductance regulator gene (CFTR), chymotrypsinogen C (CTRC),¹⁷ calcium-sensing receptor gene (CASR),¹⁸ and gamma-glutamyltransferase 1 gene (GGT1)¹⁹ have all been elucidated as conferring a susceptibility to CP development. Conversely the anionic trypsinogen gene PRSS2 may confer a protective advantage against the development of pancreatitis.

Clearly, the etiology of pancreatitis is variable, complex, and incompletely understood.

Figure 54-1. Three-hit hypothesis for pathophysiology of chronic pancreatitis. NGF, nerve growth factor. Adapted from Whitcomb DC. Genetic risk factors for pancreatic disorders. *Gastroenterology* 2013;144:1292–1302.

PATHOPHYSIOLOGY

The pathophysiology of CP is not well elucidated. A theory known as the “three-hit hypothesis” holds that (1) a stochastic event occurs resulting in (2) inappropriate trypsin activation causing acute pancreatitis. The patient then has (3) an unfavorable immunologic response to the inflammation resulting in fibrosis and CP (Fig. 54-1).²⁰ Environmental factors (e.g., alcohol and tobacco) are implicated as the inciting events to this cascade, with potential key modulating factors including genetics and the histologic milieu.

Insights into pathophysiology of pancreatitis have occurred through advances in cellular basic science. PSCs are causative in pancreatic fibrogenesis. PSCs are residents of the healthy pancreas that become activated by inflammatory cytokines during pancreatitis to become myofibroblast-like cells, producing extracellular matrix in the interstitial space.²¹ In addition, several matrix metalloproteinases are implicated in altering extracellular matrix remodeling and collagen degradation, enhancing fibrogenesis and irreversibly altering the organ architecture to a diseased, fibrotic pancreas.²²

The pathophysiology of the CP pain syndrome is not well delineated and is likely multifactorial.

Classically, pancreatic ductal obstruction due to fibrosis and resulting in elevated intraductal pressures has been implicated as a primary cause for pain. Additionally, pancreatic capsular and parenchymal fibrosis resulting in intracapsular hypertension and ischemia, create a “pancreatic compartment syndrome,” and has been theorized to result in pain. More recent theories have focused on peripancreatic neuropathy. On a histologic level, peripancreatic neuronal hypertrophy as well as infiltration of periaxonal tissue with inflammatory cells is evident.^{23,24} Increased presence of the “pain neurotransmitters” is identified including calcitonin gene-related peptide and substance P, stimulated by nerve growth factor.²⁵ These changes in the peripancreatic neuronal milieu may result in peripheral and central neural sensitization and undoubtedly contribute to the CP pain syndrome. The pancreas has a uniquely villainous role in abdominal pain syndromes. No other visceral organ can match it in terms of pain severity. Neural remodeling precipitated by pancreas-synthesized tachykinins may lead to centralization of pain that is precipitated by extra pancreatic stimuli. The “phantom pancreatitis” pain that occurs after total pancreatectomy (TP) is related to centralization of pain pathways and is a reminder of the vast intersecting neuronal web of the pancreas and the foregut.

CLINICAL PRESENTATION

2 The primary presentation of CP is severe, intractable epigastric abdominal pain that radiates into the back. The classic pain is daily and constant with periods of exacerbation. Patients typically describe pancreatitis pain as if someone is slowing twisting a knife into the epigastrium and interscapular region. Patients often have associated gut dysfunction, with nausea, emesis, and difficulty tolerating a diet consistently, particularly during pain episodes. Pain and nausea are frequently precipitated by ingestion of a fatty meal or less commonly a high protein meal. Patients may develop endocrine failure (pancreatogenic diabetes, type 3c) and exocrine pancreatic insufficiency (EPI) over time. Less often, patients may present with an acute complication of CP such as biliary or duodenal obstruction, a pancreatic pseudocyst, pancreatic ascites, mesenteric venous thrombosis, or mesenteric arterial pseudoaneurysm (Table 54-1).

On physical examination, patients may generally appear malnourished and underweight. Abdominal tenderness in the epigastrium may be elicited. Significant laboratory values to be examined include chemistries to evaluate for dehydration and acidosis. A hepatic panel may reveal elevated alkaline phosphatase or direct bilirubin, indicating biliary obstruction, or hypoalbuminemia from chronic malnutrition. Serum amylase and lipase may be elevated or may be normal during pain exacerbations in advanced disease.

Table 54-1 Complications of Chronic Pancreatitis

Pain	90%
Pseudocyst	25–30%
Biliary stricture	10–15%
Mesenteric venous thrombosis	5–10%
Duodenal stricture	4–5%
Pseudoaneurysm	2–3%
Pancreatic adenocarcinoma	2–4% ^a
Extrapancreatic malignancy	10–15%

^aRisk of pancreatic cancer is 2% after 10 years and 4% after 20 years with chronic pancreatitis.

Figure 54-2. Contrasted CT scan in venous phase, coronal images showing (A), dilated main pancreatic duct with intraductal stones and (B), significant fibrotic disease burden in the head of the pancreas with intraparenchymal and intraductal calcifications.

RADIOGRAPHIC EVALUATION

Radiography is useful in both diagnosis and treatment planning in CP. The most relevant imaging modalities include contrast-enhanced computed tomography (CT), secretin-stimulated magnetic resonance imaging with cholangiopancreatography (MRCP), endoscopic retrograde cholangiopancreatography (ERCP), and endoscopic ultrasound (EUS).

Abdominal CT can show pancreatic parenchymal changes including edema, fibrosis, or atrophy. Pancreatic ductal dilation may be evident, as well as intraparenchymal and intraductal calcifications (Fig. 54-2). CT can also be helpful in recognizing intra-abdominal complications of pancreatitis such as biliary or duodenal obstruction, pancreatic pseudocysts or ascites, or thrombosis or pseudoaneurysms of the mesenteric vasculature. Similarly, MRCP can be very useful in showing parenchymal changes in enhancement and secretion (T1-weighted images) and ductal anatomy (T2-weighted images), particularly with the addition of secretin stimulation (Fig. 54-3). With the increased capabilities of MR technology over the past couple of decades, MR imaging has largely replaced ERCP for diagnostic imaging in CP. ERCP is the classic imaging modality for CP. The ERCP Cambridge classification system, derived from an international consensus, remains the gold standard of CP staging (Table 54-2).²⁶ In the modern era, ERCP is primarily utilized as a therapeutic modality. EUS is useful for evaluation of pancreatic parenchyma and ductal anatomy, while being less invasive than ERCP. EUS also has a grading system to objectify and document pancreatitis disease severity, although the modality still maintains interobserver variability (Table 54-3). With the addition of fine needle aspiration, EUS can be helpful in the differentiation of pancreatic neoplasms from CP.²⁷

Figure 54-3. T2-weighted magnetic resonance imaging with secretin stimulation demonstrate a pathologically dilated pancreatic duct in the body of the pancreas (A), and cystic changes and dilated ducts in a fibrotic and inflammatory head of the pancreas (B).

Table 54-2 Cambridge Classification System for Chronic Pancreatitis by ERCP Imaging

Grade	Severity of Pancreatitis	ERCP Findings
1	Normal	Quality study, no abnormal features
2	Equivocal	Less than 3 abnormal branches
3	Mild	More than 3 abnormal branches
4	Moderate	Abnormal main duct and branches
5	Marked	As above with one or more of: Large cavities (>10 mm) Gross gland enlargement (>2× normal) Intraductal filling defects or calculi Duct obstruction, stricture or gross irregularity Contiguous organ invasion

ERCP, endoscopic retrograde cholangiopancreatography.
From Sarner M, Cotton PB. Classification of pancreatitis. *Gut* 1984;25:756–759.

CONSIDERATIONS IN MANAGEMENT

3 Frontline management of CP includes risk factor modification, such as alcohol and tobacco cessation. Primary medical interventions entail pain management, including adjunctive behavioral therapy, and nutritional optimization, including pancreatic enzyme replacement.

Pancreatic enzymes are the mainstay of medical management of CP despite controversy about their efficacy. Enzyme replacement is presumed to improve pain by feedback inhibition of cholecystokinin (CCK) release from the duodenum, leading to decreased pancreatic exocrine secretions. A meta-analysis of six randomized, placebo-controlled trials did not reveal a significant benefit for supplemental pancreatic enzyme therapy for pain relief.²⁸ Antioxidant therapy has been proposed as a treatment for CP, based on the theory that antioxidants will reduce oxygen free radicals and ameliorate oxidative stress and pancreatic acinar cell injury. Prospective randomized trials have shown conflicting results in antioxidant therapy for CP.²⁹

Table 54-3 EUS Criteria for Chronic Pancreatitis

Parenchymal Criteria	Normal (Low Probability)
Hyperechoic foci	0–2 criteria present
Hyperechoic strands	Indeterminate (Intermediate Probability)
Hyperechoic lobules, foci or areas	3–4 criteria present
Cyst	High Probability
Ductal Criteria	5–9 criteria present
Irregular duct contour	
Visible side branches	
Hyperechoic duct margin	
Dilated main duct	
Stone	

EUS, endoscopic ultrasound.
From Wallace MB, Hawes RH, Durkalski V, et al. The reliability of EUS for the diagnosis for chronic pancreatitis: interobserver agreement among experienced endosonographers. *Gastrointest Endosc* 2001;53:294–299.

Because CP pain is associated with extrapancreatic neuronal remodeling, neuromodulation with anticonvulsant or antidepressant medications similar to gabapentin have been utilized for CP pain management with limited success in patients with ongoing pancreatic inflammation.

Avoidance of narcotic analgesia in the management of CP pain is uniformly recommended. Analgesic management with nonsteroidal anti-inflammatory medication, acetaminophen, and tramadol is typically recommended. However, because the severity of pancreatic pain is so incapacitating, most patients who are evaluated for endoscopic or surgical management have been treated with narcotic analgesics and have developed physiologic narcotic dependence.

Behavioral therapy is a keystone of therapy in CP, particularly since many patients who are debilitated by CP are young and have previously been in good health. Behavioral modification is

effective in modulating pain perceptions in many chronic disorders. In addition, behavioral therapy is important in patients at risk for opioid misuse.³⁰

Patients who have failed medical management, have continued debilitating pain or nutritional failure, and are physiologically fit are candidates for therapeutic interventions.

ENDOSCOPIC MANAGEMENT

ERCP is the primary endoscopic modality for therapy in CP. The principle goal with ERCP is to relieve any obstructive process. Potential maneuvers include sphincterotomy, stone extraction, stricture dilation, and stenting.

EUS can be utilized for endoscopic pseudocyst drainage procedures and for celiac plexus neurolysis. Percutaneous and endoscopic-guided celiac nerve blockade has been utilized to manage CP pain. Meta-analysis studies of EUS-guided celiac plexus blockade found short-term pain relief in about one-half of the subjects.³¹

In general, the endoscopic approach is undertaken prior to consideration of surgery, given the perceived advantages of lower morbidity with a less invasive approach. Two prospective, randomized, controlled trials have compared endoscopy and surgery in patients with obstructive CP. Dite and colleagues randomized 72 patients with CP, pancreatic duct obstruction and pain to endoscopic or surgical intervention. Endoscopic therapy consisted of ERCP with 52% undergoing sphincterotomy and stenting and 23% stone removal. Operative management was 20% drainage procedure and 80% resection. At 5-year follow-up, the surgical group had a greater proportion of patients that were pain free (34% vs. 15%).³² In another study Cahen and colleagues randomized 39 patients with dilated duct CP and pain to endoscopic or surgical management. Endoscopic treatment was ERCP with sphincterotomy and stenting, and operative therapy was a drainage procedure (longitudinal pancreaticojejunostomy). At 5-year follow-up, the surgical group had a greater proportion of patients that had pain relief (80% vs. 38%, $p = 0.001$), had larger improvements in quality of life, and underwent fewer procedures, despite equivalent morbidity, length of stay, and preserved pancreatic function.^{33,34}

SURGICAL MANAGEMENT

4 Approximately two-thirds of patients with debilitating pain from CP fail medical and endoscopic managements and are candidates for consideration for operative therapy. The primary indication for surgical intervention in CP is intractable pain, and the goals of surgery are to effectively relieve pain while minimizing morbidity, including minimizing perioperative complications and preserving pancreatic parenchyma. As the underlying cause of CP pain is not well understood, operative decision-making can be difficult. The pancreatic anatomy is the primary determinant in surgical planning. Patients with a dilated (greater than 6 to 7 mm diameter) main pancreatic duct are assumed to have obstructive pathology and are candidates for a drainage-type procedure (lateral pancreaticojejunostomy, Frey procedure). In patients with a small-diameter main pancreatic duct, resection of fibrotic and poorly drained parenchyma is undertaken. Patients with head-predominant or tail-centered disease can undergo a directed partial resection. In patients with diffuse parenchymal involvement a TP with islet autotransplantation may be considered ([Algorithm 54-1](#)).

Parenchymal fibrosis associated with CP may involve adjacent organs and lead to complications requiring operative management. Other indications for surgical management of CP include terminal biliary stenosis, duodenal stenosis, gastric variceal hemorrhage due to splenic vein thrombosis, stenosis of the transverse colon, and symptomatic pancreatic pseudocysts. These complications are managed by a variety of bypass or resection procedures depending on the underlying pancreatic ductal disorder. Uncomplicated biliary stenosis is managed with biliary bypass with choledochoduodenostomy or Roux-en-Y hepaticojejunostomy.³⁵ When associated with an inflammatory mass in the head of the pancreas, pancreatic head resection may be indicated. When biliary stenosis is associated with CP and a pseudocyst in the region of the pancreatic head, pseudocyst drainage should be undertaken prior to performing biliary bypass as this may lead to resolution of the obstruction. Duodenal stenosis is usually associated with biliary stenosis and an inflammatory pancreatic head mass and is best managed with resection of the head of the pancreas.³⁶ When patient factors make resection unsafe, a double bypass is undertaken with gastrojejunostomy and biliary bypass. Gastric varices due to splenic vein occlusion are

not an indication for operation unless associated with hemorrhage. When indicated for gastric variceal bleeding complications, splenectomy is indicated. Preoperative splenic artery embolization or balloon occlusion may diminish intraoperative blood loss when splenomegaly and fibrosis in the region of the pancreatic tail make operative control of the splenic artery problematic.³⁷ Fibrosing stenosis of the transverse colon, a rare complication of CP, is managed with colonic resection and anastomosis or colostomy, depending on the condition of the patient and the condition of the pancreas.³⁸ Pancreatic pseudocysts associated with CP and ductal obstruction are managed by addressing the underlying ductal disorder with resection or drainage procedures.³⁹

Lateral Pancreaticojejunostomy

Retrograde pancreatic drainage for relapsing pancreatitis was described by Puestow and Gillesby in 1958.⁴⁰ A modification of this original drainage procedure that more closely resembles the modern-day technique of the lateral pancreaticojejunostomy (LPJ) was reported by Partington and Rochelle in 1960.⁴¹ LPJ is the classic operation for pancreatic drainage and entails opening the pancreatic duct anteriorly along its length, medially to the level of the gastroduodenal artery and laterally into the tail. The opened pancreatic duct is then cleared of stones, including into the head, and anastomosed to a Roux-en-Y jejunal limb for drainage.

Procedure-specific complications of note include intraoperative hemorrhage (due to splenic vein or gastroduodenal artery injury), postoperative hemorrhage (often from the gastroduodenal artery), and anastomotic leak (seen in 10% of cases).

Multiple retrospective single-institution case series have been reported while evaluating outcomes with LPJ, with pain-relief rates of 48% to 91%.^{42–49} Morbidity rates are low (20% on average) and endocrine and exocrine function is often preserved.⁵⁰ LPJ is an effective and safe procedure for pain relief in many patients with dilated duct pancreatitis. Recurrent pain does occur after LPJ, however, likely due to disease in the head of the pancreas. Intraductal stone disease in the head of the pancreas can be cleared with intraoperative pancreatoscopy and electrohydraulic lithotripsy, which has been shown to improve outcomes (reduced readmissions, increased pain-relief rates).⁵¹ Alternatively, combining a localized head resection with LPJ can help to reduce recidivism.

Localized Pancreatic Head Resection with Lateral Pancreaticojejunostomy

In 1987, Frey and colleagues described a localized pancreatic head resection with a lateral pancreaticojejunostomy (LR-LPJ) with the goal of achieving pancreatic ductal drainage, resection of damaged and poorly drained parenchyma in the head of the pancreas, and preservation of the duodenum to minimize postoperative gastrointestinal dysfunction. The Frey procedure combines a classic longitudinal ductotomy of the neck, body and tail of the pancreas with unroofing of the pancreatic ducts in the head and uncinate process of the pancreas with a “coring” out of the overlying ductal tissue and preservation of the pancreas parenchyma along the posterior and lateral margin of the pancreas. Frey reported initially on 50 patients, describing a morbidity of 22% and a pain-relief rate of 84%.⁵² His outcomes have been validated in modern series, both at his own institution and at others, with pain-relief rates of 62% to 88% and morbidity of 20% to 30% reported.^{53–56}

Algorithm 54-1. Algorithm for operative decision-making in chronic pancreatitis. LPJ, lateral pancreaticojejunostomy; LR-LPJ, local pancreatic head resection with lateral pancreaticojejunostomy; PD, pancreatoduodenectomy; DPPHR, duodenal-preserving pancreatic head resection; DP, distal pancreatectomy; TPIAT, total pancreatectomy with islet autotransplantation.

Pancreatic Head Resection

Pancreatoduodenectomy (PD) for CP was described as early as 1946 by Whipple.⁵⁷ In the modern era, PD is the operation of choice for patients with complicated CP and head-dominant disease. Patients may present with duodenal or biliary obstruction as well as obstructive pancreatopathy from an inflammatory mass in the head of the pancreas. Outcomes for PD include pain relief in 70% to 89% of patients, morbidity in 16% to 53%, and mortality in less than 5% in high-volume centers.^{58–61}

The pylorus preserving pancreatoduodenectomy (PPPD) was popularized by Traverso and Longmire in 1978 in an effort to maintain the physiologic benefits of a functional pylorus.⁶² PPPD has been well adopted into pancreas surgery although the purported nutritional advantages have not been evidenced.^{63–67} Some authors, however, have reported improved professional rehabilitation⁶⁴ and improved quality of life after PPPD⁶⁶ as compared to classic PD.

Duodenal preserving pancreatic head resection (DPPHR) was developed by Beger and colleagues in the 1970s in an effort to decrease the morbidity of pancreatic head resection for CP. Pain relief is reported in 77% to 88% of patients, with professional rehabilitation rates of 63% to 69%. Morbidity and mortality are acceptable at 28.5% and 1%, respectively.^{67–71} Multiple prospective randomized trials in comparing the various methods of pancreatic head resection in CP have been undertaken mostly in Germany over the past couple of decades, with no discernable advantage determined between them (Table 54-4).^{71–76} A modification of the Beger procedure was described by the group in Berne in which the neck of the pancreas is left intact in its course over the portal vein thereby diminishing the risk of portal venotomy (Fig. 54-4).^{77,78}

Distal Pancreatectomy

In patients with CP and disease localized to the body and tail of the pancreas or in patients with a main pancreatic duct stricture in the neck or body, distal pancreatectomy (DP) can be an effective means of pain relief. The majority of CP patients who are candidates for DP have severe inflammatory changes in the region of the splenic hilum, making concomitant splenectomy the most prudent course. Pain-relief rates of 57% to 84% are reported with occupational rehabilitation in 29% to 73%. Morbidity and mortality are reported in 15% to 32% and 2% to 2.2% of cases, respectively.^{79–81} Postoperative pancreatic fistula after DP is the primary morbidity of this operation and appears to be related to patient-specific factors rather than operative technique.⁸² DP appears to be applicable in approximately 9% to 25% of patients in larger series of patients undergoing surgery for CP.^{49,83}

Total Pancreatectomy

TP for CP was performed as early as 1944 by Clagett at the Mayo Clinic. Perhaps tellingly, his patient died 10 weeks after surgery of a hypoglycemic event. TP can be an effective means of pain relief in patients with diffuse small-duct pancreatitis, patients who have failed lesser surgeries, and patients with hereditary pancreatitis. Excellent pain-relief rates of 72% to 100% have been described with TP, with morbidity rates of 22% to 54% and mortality 0 to 14%. There is a requisite brittle type 3c pancreatogenic diabetes that follows TP; however, with severe diabetic control problems in 15% to 75% of patients, and in one series, half of late postoperative deaths were due to hypoglycemia.^{84,85} With TP, there is loss of not only insulin-producing beta cells but also loss of the alpha cells and other composite cells of the islet that produce hormones to maintain glucose homeostasis. As a result, patients may demonstrate an unpredictable response to exogenous insulin and importantly may develop hypoglycemic unawareness, which can be morbid.⁸⁶ Thus, TP is a good option for pain relief but the resultant diabetes is exceptionally morbid.

5 TP with islet autotransplantation (TPIAT) was described by Sutherland and colleagues at the University of Minnesota in 1978, with the goal of ameliorating the brittle diabetes after extensive pancreatectomy.⁸⁷ TPIAT has really only been performed with any regularity, however, over the past decade, and understanding of long-term outcomes is evolving. Pain-relief rates of 72% to 86% have been reported and patients have a significantly improved quality of life. Morbidity rates of 47% to 55% are reported, with 1.4% to 6% mortality, and insulin independence in 10% to 40% after islet transplant.^{88–91} Insulin independence after TPIAT correlates with the number of islet equivalents per kilogram harvested^{89,91} and transplanted islet function appears to be durable, with outcomes reported for more than 13 years.⁹² TPIAT has been safely and effectively performed in children with hereditary pancreatitis, with insulin independence in 55%.⁹³ While this therapy holds promise, long-term outcomes data are currently lacking.

PD, pancreatoduodenectomy; DPPHR, duodenal-preserving pancreatic head resection; PPPD, pylorus-preserving pancreatic head resection; LRLPJ, local resection pancreatic head with longitudinal pancreaticojejunostomy.

Laparoscopic Surgery for Chronic Pancreatitis

Laparoscopy began in pancreas surgery with laparoscopic staging for pancreatic cancer. The development of endoscopic stapler technology in the mid-1990s allowed for pancreatic resections to be developed. In 1996, Gagner reported his experience with laparoscopic distal pancreatectomy.⁹⁴ Due to the recent epidemic of incidentally discovered low-grade pancreatic neoplasms, experience with laparoscopic DP has matured rapidly, and now it is currently the most commonly performed laparoscopic pancreatic resection. A large multicenter group reported on 667 distal pancreatectomies with 159 (24%) laparoscopic, and 14 (9%) were for CP. The authors reported lower blood loss, length of stay and morbidity with laparoscopy, and equivalent operative times and pancreatic fistula rates.⁹⁵ A recent meta-analysis of studies reporting experience with laparoscopic DP, including greater than 1,800 cases, showed similar advantages with laparoscopy, while maintaining quality.⁹⁶ While laparoscopic DP is arguably now the standard approach to resection of benign or low-grade neoplasms its wide application in patients with CP is still in evolution, as these cases are more technically challenging due to the distorted anatomy and loss of tissue planes in CP. Laparoscopic LPJ has been described by several authors and is technically feasible.⁹⁷ Success rate for the minimally invasive approach in this operation increases as the size of the pancreatic duct increases. The laparoscopic PD is being performed at many

academic centers, mostly for malignant disease, but in a few with CP. The authors report reasonable operative times (median 357 to 368 minutes), blood loss (75 to 240 cc), morbidity (26.7% to 42%), and pancreatic fistula rates (6.7% to 18%).^{98–100} The limitations of laparoscopic PD in CP are similar to those with laparoscopic DP, with the associated technical challenges of operating on a fibrotic gland.

CONCLUSIONS

CP is a complex disease, challenging in diagnosis and management. Notable recent progress has been made in understanding the underlying pathophysiology, including genetic causes and cellular and biochemical mechanisms, with much still to be learned. Surgery can be beneficial in many patients with debilitating pain from CP. Evolving surgical therapies, such as TPIAT and minimally invasive techniques, are promising.

Chapter 55

Neoplasms of Exocrine Pancreas

Attila Nakeeb, Michael G. House, and Keith D. Lillemoe

Key Points

- 1 Recent evidence supports that pancreatic ductal adenocarcinoma arises from precursor lesions referred to as pancreatic intraepithelial neoplasia (PanIN) with progression from proliferative lesions without nuclear abnormality to carcinoma in situ, known as PanIN-3.
 - 2 Intraductal papillary mucinous neoplasms (IPMNs) are intraductal mucin-producing tumors that range from benign adenomas to invasive carcinoma.
 - 3 Contrast-enhanced computed tomography (CT) is the preferred noninvasive imaging test for the diagnosis and staging of pancreatic cancer.
 - 4 Perioperative mortality rates following pancreatoduodenectomy have fallen to the range of 2% to 5% although perioperative complications occur in approximately 40% of patients.
 - 5 Survival after pancreatoduodenectomy for pancreatic cancer is approximately 20% at 5 years with factors influencing survival including tumor size, margin status, and lymph node status.
 - 6 Adjuvant chemotherapy is beneficial for patients following resection of pancreatic cancer.
 - 7 Endoscopic palliation of patients with incurable pancreatic cancer located in the head may require biliary and duodenal stenting.
 - 8 Patients found to be unresectable at laparotomy for head of pancreas cancer should be considered for biliary bypass, gastrojejunostomy, and chemical splanchnicectomy to palliate the symptoms of jaundice, duodenal obstruction, and pain, respectively.
-

INTRODUCTION

Pancreatic cancer is the fourth leading cause of cancer-related death in the United States and second only to colorectal cancer as a cause of gastrointestinal cancer-related death. The overall 5-year survival for patients with pancreatic cancer is 7%.¹ Surgical resection offers the only chance for long-term cure. Unfortunately, because of the late presentation, only 15% to 20% of patients are candidates for surgical intervention. Five-year survival after pancreaticoduodenectomy (PD) is about 25% to 30% for node-negative and 10% for node-positive disease.² The nonspecific symptoms associated with early pancreatic cancer, the inaccessibility of the pancreas to examination, the aggressiveness of the tumors, and the technical difficulties associated with pancreatic surgery make pancreatic cancer one of the most challenging diseases treated by surgeons and oncologists.

In recent years, significant advances have been made in our understanding of the pathogenesis and clinical management of pancreatic cancer. This chapter will review the epidemiology and risk factors associated with pancreatic cancer, discuss recent developments in the field of molecular genetics, and provide an update on the current clinical management of pancreatic cancer.

EPIDEMIOLOGY AND RISK FACTORS

In the United States, it is estimated that nearly 48,960 new cases of pancreatic cancer will be diagnosed with almost 40,560 people dying of the disease in 2015. Pancreatic cancer accounts for 3% of all cancers in the United States and is responsible for 7% of all cancer deaths. The incidence of pancreatic cancer in the United States is 12.4 per 100,000 populations. The lifetime risk for developing pancreatic cancer is 1.5%.¹ The incidence of pancreatic cancer has slowly been increasing, with an average increase of 0.8% per year over the last 10 years (Fig. 55-1). The risk for the development of pancreatic cancer is related to age, race, sex, tobacco use, diet, and specific genetic syndromes (Table 55-1). The incidence increases

with advancing age. More than 80% of cases occur in persons between the ages of 60 and 80 years, and pancreatic cancer is rare in people younger than 40 years. The incidence and mortality rates for pancreatic cancer in African Americans of both sexes are higher than those in whites. The gender differences in pancreatic cancer have been equalizing during recent years. Pancreatic cancer is still more common in men than in women, but the incidence and mortality rates have increased in women while they have stabilized or slightly decreased in men.

Environmental and dietary factors have also been implicated as risk factors for the development of pancreatic cancer. The most consistently observed environmental risk for the development of pancreatic cancer is cigarette smoking. It has been estimated that cigarette smoking can increase the risk for pancreatic cancer between one and a half and five times. The mechanism is unknown, but carcinogens in cigarette smoke have been shown to produce pancreatic cancers in laboratory animals. In addition, autopsy studies have documented hyperplastic changes in pancreatic ductal cells with atypical nuclear patterns in smokers. Alcohol consumption does not seem to be a risk factor for pancreatic cancer despite conflicting past reports. Recent studies suggest that past studies linking pancreatic cancer to alcohol use may have been confounded by tobacco use. Similarly, coffee consumption and exposure to ionizing radiation have been shown not to be associated with an increased pancreatic cancer risk.

Several epidemiologic investigations have suggested that diet may play an important role in the development of pancreatic cancer. An apparent association has been noted between pancreatic cancer and an increased consumption of total calories, carbohydrate, cholesterol, meat, salt, dehydrated food, fried food, refined sugar, soy beans, and nitrosamines. The risks are unproven for the ingestion of fat, beta-carotene, and coffee. A protective effect has been reported for dietary fiber, vitamin C, fruits, and vegetables.³

Figure 55-1. U.S. pancreatic cancer new cases, death rate, and 5-year survival. Adapted from EER Cancer Statistics Factsheets: Pancreas Cancer. National Cancer Institute. Bethesda, MD, <http://seer.cancer.gov/statfacts/html/pancreas.html>. Accessed March 10, 2016.

In addition to well-defined genetic syndromes, a number of common conditions have been thought to be etiologic factors in the development of pancreatic cancer. An apparent association between diabetes and pancreatic cancer has been suggested. Approximately 80% of patients diagnosed with pancreatic cancer have impaired glucose metabolism, impaired glucose tolerance, or diabetes mellitus. It is unclear if alterations in glucose tolerance/metabolism are a causative factor for pancreatic cancer or represent reaction to an enlarging malignancy in the pancreas. Among patients with newly diagnosed diabetes, 0.85% went on to be diagnosed with pancreatic cancer within 3 years.⁴ Type II diabetes of at least 5 years duration has been shown to increase the risk of pancreatic cancer twofold.

The risk of pancreatic cancer has been shown to increase as body mass index increases. Examination of data from the Nurses' Health Study and the Health Professional's follow-up study show a 1.72 relative risk (95% CI 1.19–2.48) of pancreatic cancer in patients with a BMI > 30 kg/m² as compared to individuals with a BMI < 23 kg/m².

Chronic pancreatitis of any cause has been associated with a 25-year cumulative risk for the development of pancreatic cancer of approximately 4%. Other conditions for which a possible association with pancreatic cancer has been demonstrated include thyroid and other benign endocrine tumors, cystic fibrosis, and pernicious anemia.

Most cases of pancreatic cancer have no obvious predisposing factors. However, it is believed that between 5% and 10% of pancreatic cancers arise because of a familial predisposition. Six genetic syndromes have been associated with an increased risk for the development of pancreatic cancer (Table 55-2). These include hereditary nonpolyposis colon cancer, familial breast cancer associated with the *BRCA2* mutation, Peutz–Jeghers syndrome (PJS), ataxia–telangiectasia syndrome, familial atypical multiple mole–melanoma syndrome, and hereditary pancreatitis.

Table 55-1 Risk Factors for Pancreatic Cancer

	Increased Risk	Possible Risk	Unproved Risk
Demographic factors	Advancing age Male sex Black race	Geography	Socioeconomic status Migrant status
Host factors	Hereditary nonpolyposis colorectal cancer Familial breast cancer Peutz – Jeghers syndrome Ataxia – telangiectasia Familial atypical multiple-mole melanoma Hereditary pancreatitis		Peptic ulcer surgery
Environmental factors	Tobacco	Diet Occupation	Alcohol Coffee Radiation

Modified from Gold EB, Goldin SB. Epidemiology of and risk factors for pancreatic cancer. *Surg Oncol Clin North Am* 1998;7:67.

Table 55-2 Genetic Syndromes Associated with Hereditary Pancreatic Cancer

Syndrome	Mode of Inheritance	Gene	Fold Increase in Risk	Manifestation of Pancreatic Cancer
Peutz–Jeghers	AD	<i>STK11</i>	140×	Hamartomatous polyps of the gastrointestinal tract; mucocutaneous melanin macules
Hereditary pancreatitis	AD	<i>PRSS1</i>	60×	Recurrent episodes of severe pancreatitis starting at a young age
Familial pancreatic cancer	Unknown	Unknown	18×	At least one pair of first-degree relatives with pancreatic cancer
FAMMM	AD	p16	20×	Multiple nevi, atypical nevi, and melanomas
Familial breast cancer 2	AD	<i>BRCA2</i>	10×	Breast, ovarian, and pancreatic cancer
HNPCC	AD	<i>MSH2</i> <i>HLH1</i>	Unknown	Colonic, endometrial, and gastric cancers; mutator phenotype

AD, autosomal dominant; FAMMM, familial atypical multiple mole melanoma; HNPCC, hereditary nonpolyposis colorectal cancer.

MOLECULAR GENETICS

Invasive pancreatic ductal adenocarcinoma (PDAC) are genetically very complex, with wide-spread chromosome abnormalities, numerous losses and gains of large segments of DNA, and on average, more than 60 exomic alterations in each cancer.⁵ PDAC harbors an average of 63 genome alterations, of which the majority are point mutations. Four key genes are frequently altered in PDAC: *KRAS*, *CDKN2A*, *TP53*, and *SMAD4* (Table 55-3). The most common gene alteration is in *KRAS* (Kirsten rat sarcoma viral oncogene homolog), where mutations occur in codons 12, 13, and 61. More than 90% of PDAC contain *KRAS* mutations. Point mutations of the *K-ras* oncogene impair the intrinsic guanosine triphosphatase activity of its gene product; the result is a protein that is constitutively active in signal transduction *and* activates various downstream signaling pathways, including the mitogen-activated protein kinase (MAPK) cascades. Ras proteins are involved in a variety of cellular functions, including proliferation, differentiation, and survival. Cyclin-dependent kinase inhibitor 2A gene (*CDKN2A*) is also inactivated in up to 90% of PDAC, due to intragenic mutations in association with allelic loss, homozygous deletion, or hypermethylation of the gene promoter. *CDKN2A* encodes a cyclin-dependent kinase inhibitor that controls G1–S transition in the cell cycle. Inactivation of *CDKN2A* leads to the loss of an important cell cycle checkpoint and therefore relatively unchecked proliferation. *TP53* is one of the most frequently mutated genes in many types of cancer, and is inactivated in about 75% of PDAC, mainly due to point mutations or small deletions. The *p53* gene product is a DNA-binding protein that acts as both a cell-cycle checkpoint and an inducer of apoptosis. Inactivation of the *p53* gene in

pancreatic cancer leads to the loss of two important controls of cell growth: regulation of cellular proliferation and induction of cell death. *SMAD4* (*DPC4*, SMAD family member 4 gene). *SMAD4* encodes a transcription factor that mediates signaling of the transforming growth factor- β (TGF- β) superfamily. *SMAD4* is a tumor-suppressor gene that has been identified on chromosome 18q. This chromosome has been shown to be missing in nearly 90% of pancreatic cancers. The *SMAD4* gene is inactive in almost 50% of pancreatic carcinomas. The mutation appears to be a homozygous deletion in 30% of pancreatic cancers, and a point mutation in another 20% of tumors. *SMAD4* mutations are more specific than *p53* or *p16* mutations for pancreatic cancer.

Table 55-3 Genetic Alterations in Pancreatic Adenocarcinomas

Gene	Chromosome Locus	Frequency (%)
Oncogenes		
<i>K-ras</i>	12	90
Tumor suppressor genes		
<i>CDKN2A</i>	9p	95
<i>p53</i>	17p	50–75
<i>SMAD4</i>	18q	55
<i>BRCA2</i>	13q	7

Germline mutations in *BRCA2* and *CDKN2A*, and less frequently in *BRCA1*, *PALB2* and *ATM* have been identified in a small subset of patients with familial pancreatic cancer. The inactivation of *BRCA2*, which encodes a protein involved in DNA damage repair, is associated with a 3.5- to 10-fold increased risk of pancreatic cancer, as well as increased risk of breast and ovarian cancer. In addition, patients with Lynch syndrome (caused by germline mutation in one of the mismatch repair genes *MLH1*, *MSH2*, *MSH6*, or *PMS2*) and PJS (caused by germline mutation of the *STK11* gene) are at increased risk of pancreatic cancer. Approximately 4% of pancreatic cancers can be characterized by disorders of DNA mismatch–repair genes.⁶

PATHOLOGY

Tumors of the exocrine pancreas can be classified based on their cell of origin (Table 55-4). The most common neoplasms of the exocrine pancreas are ductal adenocarcinomas. Approximately 65% of pancreatic ductal cancers arise in the head, neck, or uncinate process of the pancreas; 15% originate in the body or the tail of the gland; and 20% diffusely involve the whole gland.

Solid Epithelial Tumors

Ductal Adenocarcinomas

Ductal adenocarcinomas account for more than 75% of all nonendocrine pancreatic cancers. Grossly, they are white–yellow, poorly defined, hard masses that often obstruct the distal common bile duct or main pancreatic duct. They are often associated with a desmoplastic reaction that causes fibrosis and chronic pancreatitis. Microscopically, they contain infiltrating glands of varying size and shape surrounded by dense, reactive fibrous tissue (Fig. 55-2). The epithelial cells sometimes form papillae and cribriform structures, and they frequently contain mucin. The nuclei of the cells can show marked pleomorphism, hyperchromasia, loss of polarity, and prominent nucleoli.

CLASSIFICATION

Table 55-4 Histologic Classification of 645 Cases of Primary Nonendocrine Cancer of the Pancreas

Classification	Number
Duct cell origin	572 (89%)
Duct cell adenocarcinoma	494
Giant cell carcinoma	28
Adenosquamous carcinoma	20
Microadenocarcinoma	16
Mucinous carcinoma	9
Mucinous cystadenocarcinoma	5
Acinar cell origin	8 (1%)
Acinar cell carcinoma	7
Cystadenoma	1
Uncertain histogenesis	61 (9%)
Pancreaticoblastoma	1
Papillary and cystic neoplasm	1
Mixed type – duct and islet cells	1
Unclassified	58
Connective tissue origin	4 (1%)

Bell RH. Neoplasms of the exocrine pancreas. In: Greenfield LJ, Mulholland MW, Oldham KT, eds. *Surgery: Scientific Principles and Practice*. 2nd ed. Philadelphia, PA: Lippincott-Raven; 1997:901, with permission.

Ductal adenocarcinomas tend to infiltrate into vascular, lymphatic, and perineural spaces. At the time of resection, most ductal carcinomas have already metastasized to regional lymph nodes. In addition to the lymph nodes, PDAC frequently metastasize to the liver (80%), peritoneum (60%), lungs and pleurae (50% to 70%), and adrenal glands (25%). They also can directly invade the duodenum, stomach, transverse mesocolon, colon, spleen, and adrenal glands.

1 The histologic examination of a pancreas resected for cancer frequently reveals the presence of precursor lesions in the pancreatic ducts and ductules adjacent to the cancer. This suggests that much like colon cancer, which arises from benign adenomas, pancreatic cancer may also demonstrate progression to malignant from benign precursor lesions. These precursor lesions are referred to as pancreatic intraepithelial neoplasia (PanIN). Briefly, PanIN-1A and PanIN-1B are proliferative lesions without remarkable nuclear abnormality that have a flat and papillary architecture, respectively. PanIN-3 is associated with severe architectural and cytonuclear abnormalities, but invasion through the basement membrane is absent. The older term for PanIN-3 includes carcinoma in situ (CIS). PanIN-2 is an intermediate category between PanIN-1 and PanIN-3 and is associated with a moderate degree of architectural and cytonuclear abnormality.⁷ Several lines of evidence suggest that PanINs are precursors of infiltrating pancreatic cancer: PanINs are often found in association with ductal adenocarcinomas, three-dimensional mapping techniques that demonstrated a stepwise transformation from mild dysplasia to severe dysplasia in pancreatic duct lesions, and PanINs demonstrate some of the same genetic changes seen in infiltrating adenocarcinomas, most notably activating point mutations in codon 12 of *K-ras* and mutations in the *p16* and *p53* tumor-suppressor genes.

Figure 55-2. Microscopic appearance of ductal adenocarcinoma of the head of the pancreas demonstrating glands from an adenocarcinoma embedded in a fibrous matrix.

Adenosquamous Carcinomas

Adenosquamous carcinoma is a rare variant of ductal adenocarcinoma that shows both glandular and squamous differentiation. This variant appears to be more common in patients who have undergone previous chemoradiation therapy. The biologic behavior of adenosquamous carcinoma appears to be similar to that of ductal adenocarcinoma, with similar rates of perineural invasion, lymph node

metastases, and dissemination.

Acinar Cell Carcinomas

Acinar cell carcinomas account for only 1% of pancreatic exocrine tumors. Acinar tumors are typically smooth, fleshy, lobulated, hemorrhagic, or necrotic. Histologically, they form acini, and the cells display an eosinophilic, granular cytoplasm. Immunohistochemical staining demonstrates expression of trypsin, lipase, chymotrypsin, or amylase. These tumors are more common in males with a male-to-female predominance of approximately 3:1. The age of diagnosis is usually in the fifth to seventh decades. These tumors tend to be larger than ductal adenocarcinomas, often being larger than 10 cm. Although data are limited, it appears that patients with acinar cell carcinoma have a slightly better prognosis than patients with ductal carcinoma.⁸ Therefore, surgical resection is the treatment of choice.

Giant Cell Carcinomas

Giant cell carcinomas account for less than 1% of nonendocrine pancreatic cancers. They tend to be large, with average diameters greater than 15 cm. Microscopically, they contain large, uninucleated or multinucleated tumor cells, many of which are pleomorphic. The nuclei contain prominent nucleoli and numerous mitotic figures. Giant cell carcinomas are associated with a poorer prognosis than ductal adenocarcinomas. There is a variant of giant cell carcinoma termed *giant cell carcinoma with osteoclast-like giant cells*. These lesions tend to be well circumscribed with nonpleomorphic giant cells and are less aggressive than standard giant cell carcinomas.

Pancreatoblastoma

Pancreatoblastomas occur primarily in children ages 1 to 15 years. Pancreatoblastomas contain both epithelial and mesenchymal elements. The epithelial component appears to arise from acinar cells. The tumors are typically larger than 10 cm and often contain areas of degeneration and hemorrhage. The prognosis appears to be more favorable than that for typical ductal adenocarcinoma if the tumor can be resected.

Cystic Epithelial Tumors

Cystic neoplasms also arise from the exocrine pancreas. Cystic neoplasms are less common than ductal adenocarcinomas, tend to occur in women, and are evenly distributed throughout the gland. Many pancreatic and peripancreatic cysts are actually benign inflammatory pseudocysts. It is important to identify cystic neoplasms because their management is very different from that of nonneoplastic cysts. With advancements in imaging technology, cystic lesions of the pancreas are being detected with increased frequency. With routine application of cross-sectional imaging to early diagnostic processes in medicine, pancreatic cysts are often detected incidentally.⁹ Although many of these lesions are small and asymptomatic, they can have malignant potential. Therefore, the management of these patients is complex, and knowledge of pancreatic cyst natural history and predictors of neoplasia are important.

Serous Cystic Neoplasms

Serous cysts are epithelial neoplasms composed of uniform cuboidal glycogen-rich cells that usually form numerous small cysts containing serous fluid. Serous cystadenomas or microcystic adenomas are more common in women than in men (3:1 preponderance). These tumors can vary from a few centimeters to more than 10 cm in size. Twenty-five percent to 30% of patients are asymptomatic; however, most patients present with symptoms such as abdominal or epigastric pain, dyspepsia, nausea, or vomiting. Serous cystadenomas can be located anywhere in the pancreas – head, body, or tail – and usually do not communicate with the pancreatic ducts. Plain computed tomography (CT) shows a honeycomb pattern of microlacunae, with thin septa separating different segments. Serous cystic neoplasms can have a sunburst pattern of central calcification, which is seen in 10% to 30% of cases. Grossly, they appear as spongy, well-circumscribed, multiloculated cysts. Microscopically, they consist of a layer of simple cuboidal cells separated by dense fibrous bands. Most serous cystic neoplasms are benign, although malignant behavior has been reported rarely (<1% with metastases to the liver or peripancreatic lymph nodes). Symptomatic cysts or cysts that cannot be differentiated from other potentially malignant cysts should undergo surgical excision.

Mucinous Cystic Neoplasms

Mucinous cystic neoplasms (MCNs) are neoplasms composed of mucin-producing epithelial cells associated with an ovarian-type of stroma. These cysts usually do not communicate with the larger

pancreatic ducts. MCNs are relatively uncommon but account for almost 30% of all cystic neoplasms. The mean age at diagnosis is between 40 and 50 years. MCNs are more common in women with a female-to-male ratio of 9:1. Most patients with MCNs present with vague abdominal symptoms that include epigastric pain or a sense of abdominal fullness. The majority (70% to 90%) of MCNs arises in the body or tail of the pancreas, and only a minority (10% to 30%) involves the head of the gland. Microscopically, the cysts are lined by tall columnar mucin-producing epithelium. These columnar cells have basal nuclei and abundant intracytoplasmic apical mucin and can form flat sheets or papillae. The walls of the cysts contain a very distinctive “ovarian-type” stroma. This stroma is composed of densely packed spindle cells with sparse cytoplasm and uniform elongated nuclei. All MCNs are considered to be premalignant lesions and should be completely resected to prevent progression to malignancy.

Invasive mucinous cystadenocarcinomas are MCNs associated with an invasive carcinoma, whereas noninvasive mucinous neoplasms can be categorized into MCNs with low-grade dysplasia (adenoma), MCNs with moderate dysplasia (borderline) neoplasms, and MCNs with high-grade dysplasia (carcinoma in situ) based on the degree of architectural and cytologic atypia of the epithelial cells. In surgical series between 15% and 30% of all MCNs are associated with invasive carcinoma. Patients with mucinous cystadenocarcinomas tend to be 5 to 10 years older than patients with benign MCNs. The extent of invasive and in situ carcinomas in MCNs can be very focal. Therefore, a benign diagnosis cannot be established on biopsy alone and the lesions should be completely resected. The prognosis for patients with resected benign or borderline tumors is excellent. Patients with mucinous cystadenocarcinoma tend to do better than patients with ductal adenocarcinoma, with a 5-year survival of approximately 50%.

Intraductal Papillary-Mucinous Neoplasms

Intraductal papillary-mucinous neoplasms (IPMNs) are intraductal mucin-producing neoplasms with tall, columnar, mucin-containing epithelium with or without papillary projections. These neoplasms extensively involve the main pancreatic ducts and/or major side branches. In addition, IPMNs lack the ovarian stroma characteristic of MCNs. Similar to the well-defined adenoma–carcinoma sequence in PDAC (PanIN to invasive ductal carcinoma), IPMNs seem to follow a similar pattern progressing from IPMN with low-grade dysplasia to invasive carcinoma. Microscopically, they consist of papillary projections lined by columnar mucin-secreting cells. They show varying degrees of cellular atypia. The noninvasive IPMNs are graded on the basis of greatest degree of dysplasia and classified into low-grade, moderate-grade, and high-grade dysplasia or carcinoma in situ. Invasive IPMNs are either colloid or tubular, with the latter having a worse prognosis. The mean age of patients with invasive carcinoma is approximately 5 years older than patients with noninvasive IPMNs suggesting an approximately 5-year lag period for progression to malignancy. Further histologic subtyping of epithelial differentiation is based on the cell lineage, the morphology of the papillae, and the immunophenotype, and includes classification into intestinal, gastric, pancreaticobiliary, and oncocytic subtypes.

IPMNs are subclassified as main- and branch-duct types and as a mixed type that contains elements of both. Main-duct IPMN is characterized by involvement of the duct of Wirsung, which is dilated to more than 1 cm in diameter. Branch-duct IPMN originates in the side branches of the pancreatic ductal system and appears as a multilobular cystic lesion communicating with a nondilated main pancreatic duct. Typically, branch-duct IPMN occurs in the uncinate process–head of the gland, but it can also be seen in the neck and distal pancreas. If the main duct is dilated with synchronous involvement of the branch ducts, it is described as a mixed IPMN.

IPMNs are usually found in individuals in their 60s to 80s. Some patients may experience symptoms that include: abdominal pain, steatorrhea, weight loss, jaundice, diabetes, and chronic pancreatitis. A substantial number of these lesions are also detected as incidental findings on cross-sectional imaging studies performed for other indications. IPMNs appear to be more common in the head, neck, and uncinate process of the pancreas but can be found diffusely throughout the whole gland. CT scans will typically reveal a cystic mass in the head of the pancreas that appears to communicate with the pancreatic ductal system. On endoscopy, mucin can be seen oozing from the ampulla of Vater. Endoscopic retrograde cholangiopancreatography (ERCP) can be used to confirm that the cysts communicate with the pancreatic ducts.

MCNs are the main entity to consider in the differential diagnosis of IPMNs (Table 55-5). Two morphologic features distinguish IPMNs from MCNs: IPMNs communicate with ducts, mucinous cysts do not; IPMNs also lack an ovarian stroma that is present in mucinous cysts. In addition, mucinous cysts are usually seen in the tail of the pancreas and occur in middle-aged women, whereas IPMNs are found in the head of the pancreas and occur in older individuals of either sex.

As noted, IPMNs represent a continuum of disease from benign to malignant. In a large series of resected IPMNs from the Johns Hopkins Hospital,¹⁰ the prognosis for the benign forms of the disease appears to be significantly better than for invasive IPMNs with 1-, 2-, and 5-year actuarial survivals of 97%, 94%, and 77%, respectively. Although invasive IPMNs are associated with disease progression and death, the prognosis remains markedly better than for invasive ductal carcinoma of the pancreas with survivals of 72%, 58%, and 43% at 1, 2, and 5 years, respectively. It is unclear if this fact is due to earlier presentation or differences in tumor biology.

DIAGNOSIS

Table 55-5 Comparison between Mucinous Cystic Neoplasm (MCN) and Intraductal Papillary Mucinous Neoplasm (IPMN)

	MCN	IPMN
Age (years)	40–50	60–80
Gender	More common in females	More common in males
Location	Body/tail	Head
Communicates with pancreatic duct	No	Yes
Mucin at ampulla	No	Yes
Ovarian like stroma	Yes	No

2 International consensus guidelines for the management of IPMNs have been developed.¹¹ CT or MRI with MRCP is recommended for imaging IPMNs. IPMNs are classified as having either “high-risk stigmata” or “worrisome features.” High-risk stigmata include obstructive jaundice in the setting of a cyst in the head of the pancreas, a main duct >10 mm, or a cyst with a solid enhancing component in the wall. Worrisome features include cyst >3 cm, thickened enhanced cyst walls, nonenhanced mural nodules, main duct size between 5 and 9 mm, abrupt change in the MPD caliber with distal pancreatic atrophy, and lymphadenopathy. All cysts with “worrisome features” and cysts of >3 cm without “worrisome features” should undergo endoscopic ultrasonography (EUS), and all cysts with “high-risk stigmata” should be resected. If no “worrisome features” are present, no further initial work-up is recommended, although surveillance is still required ([Algorithm 55-1](#)).

The goal of surgical therapy for IPMNs should be a complete surgical resection yielding negative margins for all invasive and noninvasive disease. Unlike those patients with completely resected noninvasive MCNs (who are routinely cured), patients with completely resected noninvasive IPMNs should undergo careful follow-up and surveillance for the development of recurrent disease. Furthermore, patients with resected invasive IPMNs should also undergo careful follow-up and surveillance as they, too, remain at risk for the development of recurrent disease.

Solid-Pseudopapillary Tumor

Solid-pseudopapillary tumors (SPTs), also termed solid and cystic tumors, papillary cystic tumors, *Hamoudi tumors*, and *Frantz tumor* occur primarily in women in their third to fourth decades of life. Grossly, the masses range from 5 to 15 cm in diameter. Radiologically, they present as a well-demarcated heterogeneous mass with solid and cystic components, with a peripheral capsule which rarely shows calcification. EUS-guided fine needle aspiration (FNA) or core biopsy is often diagnostic, showing uniform cells forming microadenoid structures, branching, and papillary clusters with delicate fibrovascular cores. Most SPTs exhibit a benign behavior, and even the less than 20% that have vascular or perineural invasion, lymph node involvement or liver metastases can have a very indolent course. The overall 5-year survival is close to 97% in patients undergoing surgical resection.

Algorithm 55-1. International consensus guidelines for the management of IPMNs. From Tanaka M, Fernandez-del Castillo C, Adsay V, et al. International consensus guidelines 2012 for the management of IPMN and MCN of the pancreas. *Pancreatology* 2012;12:183–197.

CLINICOPATHOLOGIC STAGING

Accurate pathologic staging of pancreatic cancer is important for providing prognostic information to patients and for comparing the results of various therapeutic trials. The American Joint Committee on Cancer (AJCC) staging for pancreatic cancer is shown in [Table 55-6](#). This system, based on the TNM classification, takes into account the extent of the primary tumor (T), the presence or absence of regional lymph node involvement (N), and the presence or absence of distant metastatic disease (M).

DIAGNOSIS

Clinical Presentation

Many of the difficulties associated with the management of pancreatic cancer result from our inability to make the diagnosis at an early stage. The early symptoms of pancreatic cancer include anorexia, weight loss, abdominal discomfort, and nausea. Unfortunately, the nonspecific nature of these symptoms often leads to a delay in the diagnosis. Specific symptoms usually develop only after invasion or obstruction of nearby structures has occurred. Most pancreatic cancers arise in the head of the pancreas, and obstruction of the intrapancreatic portion of the common bile duct leads to progressive jaundice, acholic stools, darkening of the urine, and pruritus. Pain is a common symptom of pancreatic cancer. The pain usually starts as vague upper abdominal or back pain that is often ignored by the patient or attributed to some other cause. It is usually worse in the supine position and is often relieved by leaning forward. Pain may be caused by invasion of the tumor into the splanchnic plexus and retroperitoneum, and by obstruction of the pancreatic duct. Other digestive symptoms are also common in pancreatic cancer ([Table 55-7](#)).

Occasionally, pancreatic cancer may be discovered in an unusual manner. The onset of diabetes may be the first clinical feature in 10% to 15% of patients. An episode of acute pancreatitis may also be the initial presentation of pancreatic cancer if the tumor partially obstructs the pancreatic duct. It is important to consider a pancreatic cancer in patients presenting with acute pancreatitis, especially those

without an obvious cause for their pancreatitis (alcohol or gallstones).

The most common physical finding at the initial presentation is jaundice (Table 55-8). Hepatomegaly and a palpable gallbladder may be present in some patients. In cases of advanced disease, cachexia, muscle wasting, or a nodular liver, consistent with metastatic disease, may be evident. Other physical findings in patients with disseminated cancer include left supraclavicular adenopathy (Virchow node), periumbilical adenopathy (Sister Mary Joseph node), and pelvic drop metastases (Blumer shelf). Ascites can be present in 15% of patients.

STAGING

Table 55-6 American Joint Committee on Cancer Staging of Pancreatic Cancer, 7th Edition

Stage	T	N	M	5-Year Survival (%)
IA	T1	N0	M0	20–30
IB	T2	N0	M0	20–30
IIA	T3	N0	M0	10–25
IIB	T1, T2, T3	N1	M0	10–15
III	T4	Any N	M0	0–5
IV	Any T	Any N	M1	—
Tumor (T)				
TX: Primary tumor cannot be assessed				
T0: No evidence of primary tumor				
Tis: Carcinoma in situ				
T1: Tumor limited to the pancreas, 2 cm or less in greatest dimension				
T2: Tumor limited to the pancreas, more than 2 cm in greatest dimension				
T3: Tumor extends beyond the pancreas but without involvement of the celiac axis or the superior mesenteric artery				
T4: Tumor involves the celiac axis or the superior mesenteric artery (unresectable primary tumor)				
Regional Lymph Nodes (N)				
NX: Regional lymph nodes cannot be assessed				
N0: No regional lymph node metastasis				
N1: Regional lymph node metastasis				
Distant Metastasis (M)				
MX: Distant metastasis cannot be assessed				
M0: No distant metastasis				
M1: Distant metastasis

Laboratory Studies

In patients with cancer of the head of the pancreas, laboratory studies usually reveal a significant increase in serum total bilirubin, alkaline phosphatase, and γ -glutamyl transferase indicating bile duct obstruction. The transaminases can also be elevated but usually not to the same extent as the alkaline phosphatase. In patients with localized cancer of the body and tail of the pancreas, laboratory values are frequently normal early in the course. Patients with pancreatic cancer may also demonstrate a normochromic anemia and hypoalbuminemia secondary to the nutritional consequences of the disease. In patients with jaundice, the prothrombin time can be abnormally prolonged. This usually is an indication of biliary obstruction, which prevents bile from entering the gastrointestinal tract and leads to malabsorption of fat-soluble vitamins and decreased hepatic production of vitamin K–dependent clotting factors. The prothrombin time can usually be normalized by the administration of parenteral vitamin K. Serum amylase and lipase levels are usually normal in patients with pancreatic cancer.

A wide variety of serum tumor markers have been proposed for use in the diagnosis and follow-up of patients with pancreatic cancer. The most extensively studied of these is CA 19–9, a Lewis blood group-related mucin glycoprotein. Approximately 5% of the population lacks the Lewis gene and therefore cannot produce CA 19–9. When a normal upper limit of 37 U/mL is used, the accuracy of the CA 19–9 level in identifying patients with pancreatic adenocarcinoma is only about 80%. When a higher cutoff value of more than 90 U/mL is used, the accuracy improves to 85%, and increasing the cutoff value to 200 U/mL increases the accuracy to 95%.¹² The combined use of CA 19–9 and ultrasonography, CT, or ERCP can improve the accuracy of the individual tests, so that the combined accuracy approaches 100% for the diagnosis of pancreatic cancer. Levels of CA 19–9 have also been correlated with prognosis and tumor recurrence. In general, higher CA 19–9 values before surgery indicate an increased size of the primary tumor and increased rate of unresectability. In addition, the CA 19–9 level has been used to monitor the results of neoadjuvant and adjuvant chemoradiation therapy in patients. Increasing CA 19–9 levels usually indicate recurrence or progression of disease, whereas stable or declining levels indicate a stable tumor burden, absence of recurrence on imaging studies, and an improved prognosis.

Radiologic Investigations

Radiologic imaging plays a crucial role in the diagnosis, staging, and follow-up of patients with pancreatic cancer. In addition to identifying the primary tumor, the goals of imaging include the assessment of local and regional invasion, evaluation of lymph nodes and vascular structures, identification of distant metastatic disease, and the determination of tumor resectability. Ultrasonography, computed tomography (CT), and magnetic resonance imaging (MRI) are all useful noninvasive tests in the patient suspected of having a pancreatic cancer.

Transabdominal ultrasonography (US) will reveal a pancreatic mass in 60% to 70% of patients with cancer. Pancreatic cancer typically appears as a hypoechoic mass on US. Ultrasonography may also demonstrate dilated intrahepatic and extrahepatic bile ducts, liver metastases, pancreatic masses, ascites, and enlarged peripancreatic lymph nodes. Because helical CT is just as sensitive as ultrasonography and provides more complete information about surrounding structures and the local and distant extent of the disease, transabdominal ultrasonography has been largely replaced by CT.

Figure 55-3. Computed tomogram of the abdomen of a patient with adenocarcinoma of the pancreas. **A:** The obstructed and dilated common bile duct (*light arrow*) and pancreatic duct (*dark arrow*) can be seen. In the adjacent cross section **B**, a large mass is present in the head of the pancreas (*arrow*).

3 Computed tomography (CT) scanning is currently the preferred noninvasive imaging test for the diagnosis of pancreatic cancer. Pancreas protocol CT should be performed with rapid injection of intravenous iodinated contrast. Slices should be reconstructed at less than or equal to 3 mm with overlap. At least two postcontrast acquisitions, in the late arterial (or parenchymal) and venous phases are useful to assess the arteries (celiac, common hepatic, peripancreatic, and superior mesenteric arteries) and veins (portal, splenic, and superior mesenteric veins). The parenchymal phase best shows the tumor as an ill-defined hypodense mass in the pancreatic parenchyma (Fig. 55-3), while the venous phase is best for detecting liver metastases. Neutral enteral contrast such as water should be given, since this allows for better identification of the duodenal wall and results in artifact-free reformations. In many centers, no oral contrast is used. Coronal and sagittal reformations in both arterial and venous phases increase the sensitivity for determining local invasion. In addition to determining the primary tumor size, CT is used to evaluate invasion into local structures or metastatic disease.

In general, MRI offers no significant advantages over CT because of a low signal-to-noise ratio, motion artifacts, lack of bowel opacification, and low spatial resolution. MRI can be considered an alternative preoperative staging examination in patients with allergies to iodinated contrast agents and in patients with renal insufficiency. On MRI, a typical pancreatic adenocarcinoma appears hypointense on T1-weighted, unenhanced images, and has a variable appearance on T2-weighted sequences. The T2 signal of the tumor is often dependent on the amount of desmoplastic response associated with the tumor. On dynamic imaging following a gadolinium contrast injection, an adenocarcinoma enhances relatively less than the background pancreatic parenchyma in the early phase and then reveals progressive enhancement in the subsequent phases. Magnetic resonance imaging with MRCP is currently indicated for noninvasive diagnostic imaging to evaluate the biliary and pancreatic ducts and may be the optimal method to survey patients with IPMN and the pancreatic remnant after surgery.

Traditionally, the next step in the evaluation of the jaundiced patient has been cholangiography, either by the endoscopic or by the percutaneous route. If the endoscopic approach is used, the duodenum and ampulla can be visualized and biopsy specimens obtained if necessary. In addition, ERCP allows for direct imaging of the pancreatic duct. The sensitivity of ERCP for the diagnosis of pancreatic cancer approaches 90%. The finding of a long, irregular stricture in an otherwise normal pancreatic duct is highly suggestive of a pancreatic cancer (Fig. 55-4). Often, the pancreatic duct will be obstructed with no distal filling. Although ERCP is reliable in confirming the presence of a clinically suspected pancreatic cancer, it should not be used routinely. Diagnostic ERCP should be reserved for patients with presumed pancreatic cancer and obstructive jaundice in whom no mass is demonstrated on CT, symptomatic but nonjaundiced patients without an obvious pancreatic mass, and patients with chronic pancreatitis who develop jaundice.

EUS is a minimally invasive technique in which a high-frequency ultrasonographic probe is placed into the stomach and duodenum endoscopically and the pancreas is imaged. Tumors appear as hypoechoic areas in the pancreatic substance (Fig. 55-5). The strengths of EUS techniques for pancreatic cancer are the clarification of small lesions (<2 cm) when CT findings are questionable or negative, detection of malignant lymphadenopathy, detection of vascular involvement, and the ability to perform EUS-guided FNA for definitive diagnosis and staging. EUS is not effective in assessing metastatic disease to the liver. In patients for whom a tissue diagnosis is required (poor operative candidates or undergoing neoadjuvant therapy), EUS-guided FNA has been used to acquire tissue samples for cytologic analysis. This approach may avoid the risks of tumor seeding from percutaneous biopsy. The accuracy of EUS without FNA averages 85% for determining T-stage and 70% for determining N-stage diseases. The combination of EUS and FNA has a sensitivity of 93% and a specificity of 100% for T stage and an accuracy of 88% for N stage.¹³ At the time of diagnosis, only 10% of patients have tumors confined to the pancreas, 40% have locally advanced disease, and more than 50% have distant spread.

Figure 55-4. Endoscopic retrograde cholangiopancreatography in a patient with adenocarcinoma of the pancreas demonstrates a stricture of both the distal common bile duct and the pancreatic duct (arrow).

Figure 55-5. Endoscopic ultrasonogram of a 2.2-cm mass in the head of the pancreas. The transducer tip is located in the duodenum. The dilated common bile duct and gallbladder (GB) can be seen at the top of the image. The pancreatic duct (PD) is also dilated. The mass involves the portal vein (PV).

Percutaneous FNA of pancreatic masses is helpful in selected patients. The technique is safe and generally reliable but is of limited use in patients in whom surgical exploration for attempted resection or palliation is planned. The reasons for not using FNA or percutaneous biopsy in potentially resectable lesions are twofold. First, even after repeated sampling, a negative result does not exclude malignancy; in fact, it is the smaller and likely more curable tumors that are likely to be missed by the needle. The second concern is the potential for seeding of the tumor, either along the needle tract or with intraperitoneal spread. Percutaneous biopsy is primarily indicated in patients with unresectable cancers based on preoperative staging to direct palliative chemoradiation therapy or in patients with cancer in the head of the pancreas in whom neoadjuvant protocols are being considered. Currently, however, EUS is the preferred technique when possible in either situation.

PREOPERATIVE STAGING

The goal of preoperative staging of pancreatic cancer is to determine the feasibility of surgery and the optimal treatment for each individual patient. Specific anatomy-based CT criteria can stratify patients into four distinct groups ([Table 55-9](#)): (1) Resectable, (2) Borderline, (3) Locally advanced, or (4) Metastatic. The extent of further staging to be performed depends on the individual patient and the surgeon's preference. Historically, patients with resectable CT criteria were offered operation as the first modality of therapy followed by adjuvant chemotherapy or chemoradiotherapy. Recent advances in the efficacy of systemic chemotherapy agents have further supported the hypothetical benefits of preoperative neoadjuvant chemotherapy even for resectable tumors. Patients with borderline or locally advanced pancreatic cancer based on CT criteria should receive preoperative chemotherapy or chemoradiotherapy. Ideally, patients in these high-risk categories of disease should be offered enrollment in clinical trials investigating novel treatment agents. [Algorithm 55-2](#) outlines an algorithm for approaching patients with pancreatic cancer after complete staging and determination of resectability based on local vascular involvement according to CT findings.

STAGING LAPAROSCOPY

The use of diagnostic laparoscopy in pancreatic cancer remains controversial. Proponents believe that laparoscopy can identify a substantial number of unresectable patients with advanced disease and, therefore, should be uniformly applied to all patients with potentially resectable tumors.¹⁴ On the other hand, opponents believe that the inherent cost of such a practice far outweighs the benefit to the small number of patients in whom diagnostic laparoscopy is useful. The liver and peritoneum are the most common sites of distant spread of pancreatic carcinoma. Once distant metastases have developed, survival is so limited that a conservative approach is usually indicated. Liver metastases larger than 1 cm in diameter can usually be detected by CT, but approximately 30% of these metastases are smaller

and therefore may not be routinely detected. Moreover, peritoneal and omental metastases are usually only 1 to 2 mm in size and frequently can be detected only by direct visualization. With the recent improvements in CT imaging, the rate of unsuspected positive peritoneal findings approaches 10% to 15% for all patients. The percentage however varies with tumor location. Patients presenting with obstructive jaundice secondary to tumors in the head of the pancreas typically have only a 15% to 20% incidence of unexpected intraperitoneal metastasis after routine staging studies. In contrast, unexpected peritoneal metastasis is found in up to 50% of patients with cancer of the body and tail of the pancreas.¹⁵

Selective use of staging laparoscopy should be considered for patients at high risk of occult metastatic disease (Table 55-10). The information gained from preoperative staging provides the basis for planning therapy for each individual patient. If the results of preoperative staging with CT/MRI and laparoscopy show localized disease, resectability rates may approach 90% for tumors in the head of the pancreas.

Table 55-9 Preoperative Staging based on CT Findings

<i>Metastatic</i> Evidence of metastatic spread (typically to the liver, peritoneum, or lung)
<i>Resectable</i> No evidence of extrapancreatic disease Patent SMV/PV Normal tissue plane between tumor and the celiac, CHA, or the SMA.
<i>Borderline resectable</i> Patent SMV/PV, or short segment occlusion if reconstructable Evidence of tumor abutment (<180 degree or 50% vessel circumference) against celiac, CHA, or SMA
<i>Locally advanced</i> SMV/PV occlusion with no option for reconstruction Arterial encasement (>180 degree or 50% vessel circumference) of celiac, CHA, or SMA

Algorithm 55-2. Management strategy based on CT criteria for resectability of pancreatic cancer.

RESECTION OF PANCREATIC CARCINOMA

Carcinoma of the Head, Neck, or Uncinate Process

In 1912, Kaush¹⁶ reported the first successful resection of the duodenum and a portion of the pancreas for an ampullary cancer. In 1935, Whipple et al.¹⁷ described a technique for radical excision of a periampullary carcinoma. The operation was originally performed in two stages. A cholecystogastrostomy to decompress the obstructed biliary tree and a gastrojejunostomy to relieve gastric outlet obstruction comprised the first stage. The second stage was performed several weeks later when the jaundice had resolved and the nutritional status had improved. During the second stage, an en bloc resection of the second portion of the duodenum and head of the pancreas was performed without reestablishing pancreatic–enteric continuity. Although earlier contributions had been made, the report

by Whipple et al. began the modern-day approach to the treatment of pancreatic carcinoma.

DIAGNOSIS

Table 55-10 Signs of High Risk of Occult Metastatic Disease

Large primary tumors
Lesions in the neck, body, or tail of the pancreas
Equivocal radiographic findings suggestive of occult distant metastatic disease
Low-volume ascites
CT findings indicating possible carcinomatosis
Small hypodense regions in the hepatic parenchyma that suggest hepatic metastases that are not amenable to percutaneous biopsy
Subtle clinical and laboratory findings suggesting more advanced disease (e.g., marked hypoalbuminemia and/or weight loss, significant increases in CA19-9 level, and relatively severe pain requiring narcotic analgesia)

CT, computed tomography.

The operative management of pancreatic cancer consists of two phases: first, assessing tumor resectability and then, if the tumor is resectable, completing a PD and restoring gastrointestinal continuity. After the abdomen has been opened through an upper midline or bilateral subcostal incision, a careful search for tumor outside the limits of a pancreaticoduodenal resection should be carried out. The liver, omentum, and peritoneal surfaces are inspected and palpated, and suspect lesions are sampled and specimens submitted for frozen-section analysis. Next, regional lymph nodes are evaluated for tumor involvement. The presence of tumor in the periaortic lymph nodes of the celiac axis indicates that the tumor is beyond the limits of normal resection. However, the presence of tumor-bearing lymph nodes that normally would be incorporated within the resection specimen does not constitute a contraindication to resection.

Once distant metastases have been excluded, the primary tumor is assessed in regard to resectability. Local factors that preclude pancreaticoduodenal resection include retroperitoneal extension of the tumor to involve the inferior vena cava or aorta or direct involvement or encasement of the superior mesenteric artery, hepatic artery, and celiac axis. Involvement of the superior mesenteric vein (SMV), or portal vein can be managed with venous resection and reconstruction in select cases. The technical aspects of determining local resectability begin with a Kocher maneuver and mobilization of the duodenum and head of the pancreas from the underlying inferior vena cava and aorta. Once the duodenum and head of the pancreas are mobilized sufficiently, the surgeon's hand can be placed under the duodenum and head of the pancreas to palpate the relationship of the tumor mass to the superior mesenteric artery. Inability of the surgeon to identify a plane of normal tissue between the mass and the arterial pulsation indicates direct tumor involvement of the superior mesenteric artery, and the possibility of complete tumor resection is eliminated.

The final step to determine resectability involves dissection of the superior mesenteric and portal veins to rule out tumor invasion. Identification of the portal vein can be simplified greatly if the common hepatic duct is divided and reflected early in the dissection. Once the hepatic duct has been divided, the posteriorly located portal vein can be identified easily. After the anterior surface of the portal vein is dissected posterior to the neck of the pancreas, the next step is to identify the SMV and dissect its anterior surface. This is done most easily by extending the Kocher maneuver past the second portion of the duodenum to include the third and fourth portions of the duodenum. During this extensive kocherization, the first structure that one encounters anterior to the third portion of the duodenum is the SMV. Alternatively the SMV may also be identified by tracing either the middle colic vein or the right gastroepiploic vein back to the SMV after entering the lesser sac thru the gastrocolic ligament. The anterior surface of the SMV then can be cleaned rapidly and dissected under direct vision by retracting the neck of the pancreas anteriorly. The dissection is continued until it connects to the portal vein dissection from above.

Most experienced pancreatic surgeons, at this point, proceed with a PD without obtaining a tissue diagnosis. The clinical presentation, results of preoperative CT and cholangiography, and operative findings of a palpable mass in the head of the pancreas surpass the ability of an intraoperative biopsy to define the diagnosis of malignancy.

Having excluded regional and distant metastases and demonstrated no tumor involvement in major vascular structures, the surgeon can proceed with PD with a high degree of certainty that the tumor is

resectable. In the pylorus-preserving modification of PD, the duodenum is first mobilized and divided approximately 2 cm distal to the pylorus. If a classic Whipple procedure is to be performed, the stomach is divided to include approximately 40% to 50% of the stomach with the resected specimen. The gastroduodenal artery is exposed, ligated, and divided near its origin at the common hepatic artery. It is always important to confirm, before ligation, that the structure to be ligated is indeed the gastroduodenal artery and not a replaced right hepatic artery. Next, the neck of the pancreas is divided, with care taken to avoid injury to the underlying superior mesenteric and portal veins. The portal and superior mesenteric veins are then dissected from the uncinate process and head of the pancreas. At this point, the fourth portion of the duodenum and the proximal jejunum are mobilized, with the proximal jejunum divided approximately 10 cm distal to the ligament of Treitz. The proximal jejunum and fourth portion of the duodenum are passed under the superior mesenteric vessels to the right, and the uncinate process is dissected from the superior mesenteric artery clearing all of the tissue along the right border of the artery. The course of the superior mesenteric artery should be clearly identified to avoid injury to this structure. At this point, the specimen consisting of the gallbladder and common bile duct; the head, neck, and uncinate process of the pancreas; the entire duodenum; and the proximal jejunum (and the distal stomach for a traditional Whipple procedure) is freed completely and removed from the operative field (Fig. 55-6). Margins should be inked to facilitate pathologic analysis of the specimen.

Jang et al. ²²	2014	Standard	83	5.9	32	0	25
		Extended	84	7.0	45	2.3	23

There are a number of techniques for restoring gastrointestinal continuity after a pancreaticoduodenal resection. Our preferred technique is to bring the end of the divided jejunum through the transverse mesocolon in a retrocolic fashion and perform an end-to-side pancreaticojejunostomy. The anastomosis is begun by placing a series of interrupted 3-0 silk sutures between the side of the jejunum and the posterior capsule of the end of the pancreas. A small enterotomy is then made in the jejunum to match the size of the pancreatic duct and an inner layer of interrupted 5-0 absorbable monofilament sutures are used to create a duct-to-mucosa anastomosis. Some surgeons prefer to stent this anastomosis with either a short indwelling pancreatic stent or an externalized pancreatic stent. The anastomosis is completed with an outer layer of 3-0 silk sutures placed between the anterior pancreatic capsule and the jejunum. An alternative to this duct-to-mucosa technique is to create an enterotomy approximately the same size as the pancreatic neck and to complete a running anastomosis circumferentially around the entire gland. This technique then allows invagination of the neck 1 to 2 cm into the lumen of the bowel by the outer anterior layer of the anastomosis. The biliary–enteric anastomosis is performed 10 cm distal to the pancreaticojejunostomy. An end-to-side hepaticojejunostomy is performed with a single interrupted layer of 4-0 absorbable synthetic suture material. No T tube or stent is generally necessary. Approximately 20 cm distal to the biliary–enteric anastomosis, an end-to-side duodenojejunostomy is performed in an antecolic manner with an inner continuous layer of 3-0 absorbable synthetic suture material and an outer interrupted layer of 3-0 silk. The final reconstruction is shown in [Figure 55-6C](#).

Extent of Resection

Several technical aspects of PD remain controversial. These controversies include: (1) whether or not a radical lymph node dissection is necessary, (2) should a pylorus preserving or classic PD be performed, and (3) is there a role for laparoscopic pancreatic resections.

Several nonrandomized retrospective studies have advocated adding a radical (extended) retroperitoneal lymph node dissection to PD in an attempt to improve survival. However, results from four randomized prospective trials ([Table 55-11](#))¹⁸⁻²² have shown extended lymph node dissections not to be beneficial. The prospective trial performed by Pedrazzoli et al.¹⁸ suggested a survival advantage to extended retroperitoneal lymph node dissection in patients with positive lymph nodes. Eighty-one patients with pancreatic adenocarcinoma were randomized to either standard or radical lymphadenectomy over 3 years at six different institutions. While the two groups were similar with respect to preoperative parameters, operative morbidity, and overall survival, a subgroup analysis of the 48 patients with positive lymph nodes showed a statistically significant survival advantage for patients undergoing the extended lymph node dissection. However, the largest prospective randomized trial from the Johns Hopkins Hospital failed to demonstrate a survival advantage for a radical resection as compared with a classic PD.¹⁹ Two hundred and ninety-four patients undergoing resection for periampullary adenocarcinoma were randomized between a standard resection (pylorus preserving PD with en bloc resection of the anterior and posterior pancreaticoduodenal lymph nodes, lower hepatoduodenal lymph nodes, and nodes along the right lateral aspect of the superior artery and vein) and a radical resection (standard resection plus distal gastrectomy and retroperitoneal lymph node dissection extending from the right renal hilum to the left lateral border of the aorta and from the portal vein to the inferior mesenteric artery). The groups did not differ with respect to age, gender, site of primary tumor, lymph node status, or margin status. There were no significant differences in 1-, 3-, or 5-year and median survival when comparing the standard and radical groups ([Fig. 55-7](#)). However, the radical group had a higher overall morbidity (43% vs. 29%) with significantly higher rates of delayed gastric emptying and pancreatic fistula in addition to a longer postoperative hospital stay.

In 1978, Traverso and Longmire²³ popularized the pylorus-preserving modification of the Whipple procedure. Preserving antral and pyloric function, the pylorus-preserving Whipple procedure reduces

the incidence of troublesome postgastrectomy symptoms. A number of studies have documented that gastrointestinal function is better preserved in the pylorus-sparing modification than in the traditional operation. In addition, compared with the classic Whipple operation, the pylorus-preserving procedure is less time-consuming and technically easier to perform. Concerns exist in the use of the pylorus-preserving Whipple procedure for the management of periampullary tumors because of the possibility of compromising the already small proximal surgical margin of resection. This question has been addressed by a number of authors, and no difference appears to be found in survival among those patients treated with the pylorus-sparing Whipple procedure and those managed by the traditional Whipple resection.^{24–26} Therefore, many pancreatic surgeons favor pylorus-preserving PD because it shortens the operative time, retains the entire stomach as a reservoir, and has a similar survival rate as compared with the classic PD.

Figure 55-7. Actuarial survival for standard versus radical pancreaticoduodenectomy. From Yeo CJ, Cameron JL, Lillemoe KD, et al. Pancreaticoduodenectomy with or without distal gastrectomy and extended retroperitoneal lymphadenectomy for periampullary adenocarcinoma, part 2: randomized controlled trial evaluating survival, morbidity, and mortality. *Ann Surg* 2002;236:355–366; discussion 366–368, with permission.

In recent years, significant advances have been made in the application of minimally invasive techniques to the management of both benign and malignant pancreatic disorders. Initially, laparoscopic pancreatic surgery was limited to diagnostic staging in patients with pancreatic cancer prior to resection. More recently, minimally invasive techniques have been used to manage benign and malignant lesions of the pancreas. While laparoscopic distal pancreatic resections are being performed with increasing frequency,²⁷ the role of minimally invasive PD remains controversial. Laparoscopic or robotic PD is a technically demanding procedure due to the retroperitoneal location of the pancreas, its intimate association with surrounding gastrointestinal and major vascular structures, and the need for three separate anastomoses to complete the reconstruction. In addition, it is unclear whether an adequate cancer operation can be performed with respect to lymph node harvest and margin status in patients with malignancy. Currently, laparoscopic PD is only performed in a handful of specialized centers (Table 55-12). The procedures are performed as either robotic, pure laparoscopic, hand assisted, or as laparoscopic-assisted procedures with the resection being performed laparoscopically and the reconstruction being completed via a “mini” laparotomy or through a hand port.

Carcinoma of the Body and Tail

The surgical management of adenocarcinoma of the body and tail of the pancreas is much more limited than that of the head of the pancreas because of the extent of the disease usually present at the time of symptomatic presentation. Most patients are unable to undergo resection, based on findings of major vascular involvement on CT or peritoneal or liver metastases on laparoscopy. If an attempt at open exploration for possible cure is undertaken, the exploration should be started with a search for evidence of either metastatic disease to the liver or peritoneal implants. If this is not the case, the lesser sac is opened, and the SMV is identified as it passes under the neck of the pancreas. If this vessel is normal, and if the splenic vein does not appear to be obstructed preoperatively, a distal pancreatectomy with splenectomy is performed. The spleen is mobilized, as is the distal pancreas, and an en bloc resection of the structure, including the mass, is obtained. The resection should be extended as proximally as possible, with the transected pancreas simply oversewn. The tumor bed should be marked with the

placement of clips for postoperative radiation therapy. If, as in most cases, the tumor cannot be resected, a tissue biopsy should be performed, in addition to a chemical splanchnicectomy with alcohol for pain management. In some cases, a prophylactic gastrojejunostomy may be indicated because of the potential for obstruction by tumor at the ligament of Treitz.

Postoperative Results

4 During the 1960s and 1970s, many centers reported operative mortality following PD in the range of 20% to 40%, with postoperative morbidity rates as high as 40% to 60%. During the last three decades, a dramatic decline in operative morbidity and mortality following PD has been reported at a number of centers, with operative mortality rates in the range of 2% to 3%.³³⁻³⁵ The reasons behind this decline appear to be the following: (a) fewer, more experienced surgeons are performing the operation on a more frequent basis, (b) preoperative and postoperative care has improved, (c) anesthetic management has improved, and (d) large numbers of patients are being treated at high-volume centers.³⁶

Although the operative mortality rates for pancreatic cancer have been reduced significantly, the complication rates approach 40% (Table 55-13). Pancreatic fistula remains the most frequent serious complication following PD, with an incidence ranging from 5% to 15%. In the past, the development of pancreatic fistula after PD was associated with mortality rates of 10% to 40%. Although the incidence of pancreatic fistula following PD remains stable, the overall associated mortality rate has diminished owing to improved management. Important supportive measures include careful maintenance of fluid and electrolyte balance, parenteral nutrition, and controlling the pancreatic leak with percutaneous or intraoperative drainage.

Long-Term Survival

5 Historically, 5-year survival rates for patients undergoing resection for adenocarcinoma of the head of

the pancreas were reported to be in the range of 5%. However, recent studies have suggested an improved survival for patients following PD. In 2006, Winter et al.³⁷ reported on 1,175 patients who underwent operative resection for pancreatic adenocarcinoma. The actuarial 5-year survival for these patients was 18%, with a median survival of 18 months (Fig. 55.8). In this study, factors found to be important predictors of survival included tumor diameter (<3 cm), negative resection margin status, well/moderate tumor differentiation, and postoperative chemoradiation treatment. Patients who underwent resection with negative margins had a median survival of 20 months and a 5-year survival of 21%, whereas those with positive margins fared significantly worse, with a median survival of 14 months and a 5-year survival of 12%. The outcome was particularly favorable in the subgroup of patients with small tumors (<3 cm) who underwent margin-negative, node-negative resections; the median survival was 44 months and the 5-year survival was 43%.

ADJUVANT AND NEOADJUVANT THERAPY

6 At present, the general consensus of most surgeons treating patients with pancreatic carcinoma is that any future improvement in survival for this disease will involve improvements in systemic therapy. Despite advances in surgery and perioperative care that have resulted in markedly reduced postoperative mortality after pancreatoduodenectomy, the median survival for pancreatic cancer patients has changed minimally over the past two decades. Even with optimal surgical management, 5-year survival averages 15% to 20% for resectable disease and 3% for all stages combined. Approximately 85% of patients with resected pancreatic cancer will ultimately recur and die of their disease. These outcomes suggest that in most cases pancreatic cancer is a systemic disease at the time of diagnosis, making surgical resection alone inadequate therapy. The results of the most important randomized prospective trials of adjuvant therapy for pancreatic cancer are summarized in Table 55.14.

In 1985, the Gastrointestinal Tumor Study Group reported encouraging results from a prospective, randomized trial to evaluate the efficacy of adjuvant radiation and chemotherapy following curative resection for adenocarcinoma of the head of the pancreas.³⁸ Forty-three patients were randomized to either adjuvant therapy with radiation and 5-fluorouracil (5-FU) or no adjuvant therapy. The median survival for the 21 patients who received adjuvant therapy was 20 months, and three (14%) survived 5 years or longer. For the 22 patients who received no adjuvant therapy, the median survival was 11 months, and only 1 patient (4.5%) survived 5 years.

The randomized trial conducted by the European Organization for Research and Treatment of Cancer (EORTC),³⁹ sought to recapitulate the results of the GITSG study in 114 patients with pancreatic head lesions (observation, $n = 54$ and adjuvant treatment, $n = 60$). However, chemotherapy (5-FU) given during radiation was given as a continuous infusion (rather than via bolus) during each radiation sequence, depending on toxicity, for up to 5 days. No chemotherapy was given postchemoradiation. Fifty-six percent of patients received the intended chemotherapy dose during radiation. Patients in the chemoradiation arm had a median survival of 17.1 months versus 12.6 months in the observation arm ($p = 0.099$); 2- and 5-year overall survivals were 37% and 20%, respectively, for the experimental arm and 23% and 10%, respectively, for the control arm.

The ESPAC-1 trial published in 2004 analyzed 289 patients recruited from 53 hospitals in a 2×2 factorial design.⁴⁰ The four study groups included (1) surgery only ($n = 69$); (2) chemotherapy only ($n = 73$) consisting of 5-FU, 425 mg/m², and leucovorin, 20 mg/m², given daily for 5 days every 4 weeks for six cycles of treatment; (3) radiation therapy and 5-FU given ($n = 75$) according to the original GITSG method; and (4) both treatments ($n = 73$, chemoradiation followed by chemotherapy). The major study conclusions were that the 5-year overall survival comparisons between patients who received chemotherapy versus those that did not (21% vs. 8%, $p = 0.009$) and those that received radiation therapy versus those that did not (10% vs. 20%, $p = 0.05$). The authors concluded that adjuvant chemotherapy had a beneficial effect in resected pancreatic cancer, whereas chemoradiation had a deleterious effect. A quality-of-life questionnaire showed no difference between those that received chemotherapy and those that did not, and those that received chemoradiation and those that did not. Thus, the survival benefit of adjuvant chemoradiation for pancreatic cancer patients remains unclear, and the optimal regimen has yet to be determined.

The RTOG 9704 trial, presented in abstract form in 2006,⁴¹ contained 442 eligible patients who received adjuvant chemoradiation (5,040 cGy) given as continuous fractions with radiosensitizing doses of 5-FU. The comparisons were with the addition of either three cycles of 5-FU (one prechemoradiation, two postchemoradiation for 12 weeks) versus four cycles of gemcitabine (one prechemoradiation, three

postchemoradiation). Although the study showed no overall difference in aggregate survival, when pancreatic head lesions only were considered (eliminating study results from resected lesions in the pancreatic body or tail), both median survival (16.7 vs. 18.8 months) and overall survival at 3 years (21% vs. 31%) favored the gemcitabine arm ($p = 0.047$). The study concluded that the addition of adjuvant gemcitabine to postoperative 5-FU chemoradiation was superior to the addition of 5-FU.

Figure 55-8. Survival of patients with pancreaticoduodenectomy based on tumor size (A), lymph node status (B), margin status (C), histologic grade (D), and historical context (E). From Winter JM. Cameron JL. Campbell KA, et al. 1423 pancreaticoduodenectomies for pancreatic cancer: a single-institution experience. *J Gastrointest Surg* 2006; 10:1199–210, with permission.

TREATMENT

Table 55-14 Randomized Prospective Trials of Adjuvant Therapy for Pancreatic Cancer

Study	Treatment Arm	Median Survival (Months)	2-Year Overall Survival (%)	5-Year Overall Survival (%)
GITSG ³⁸	Surg	11	18	0
	Surg, XRT, 5-FU	18	43	19

	Surg, XRT, Gemcitabine	19	31 (3 y)	—
CONKO ⁴²	Surg	20	42	12
	Surg, Gemcitabine	22	48	23

The CONKO-1 trial,⁴² conducted in Germany and Austria, represented a randomization of 368 patients following R0 or R1 resection to either observation or an experimental arm of gemcitabine. After a median follow-up time of 53 months, the median disease-free survival was 13.9 months in the gemcitabine arm versus 6.9 months in the observation arm ($p < 0.001$). There was no difference in overall survival for the gemcitabine arm versus the control group – median survival was 22 versus 20 months. Although survival was not different, the authors concluded that postoperative gemcitabine significantly delayed the development of recurrent disease after complete resection of pancreatic cancer compared with observation alone and, thus, was supported as adjuvant therapy in resectable pancreatic cancer.

At present, many centers are utilizing preoperative neoadjuvant chemoradiation for the treatment of pancreatic cancer (Table 55-15). Neoadjuvant therapy offers several potential benefits including: (1) delivery of treatment to well-oxygenated tissue which enhances efficacy of chemoradiation, (2) downstaging can enhance ability to achieve a negative-margin resection and thereby reduce local recurrence, and (3) avoidance of surgery in patients with rapidly progressive disease. Neoadjuvant therapy can be completed without increasing the subsequent morbidity and mortality of surgical resection. The group from the M.D. Anderson Cancer Center reported on the multimodality treatment of 142 consecutive patients with localized adenocarcinoma of the pancreatic head.⁴³ A subset of 41 patients treated by preoperative chemoradiation and pancreatoduodenectomy were compared with 19 patients receiving pancreatoduodenectomy and postoperative adjuvant chemoradiation. Surgery was not delayed for any patient who received preoperative chemoradiation because of chemoradiation toxicity, but 24% of the eligible patients did not receive their intended postoperative chemoradiation because of delayed recovery following PD. The patients treated with rapid fractionation were reported to have a significantly shorter duration of treatment (median, 62.5 days) than patients who received postoperative chemoradiation (median, 98.5 days). In early follow-up, no patient who received preoperative chemoradiation experienced a local recurrence, and peritoneal recurrence developed in only 10% of these patients. Local or regional recurrence developed in 21% of patients who received postoperative chemoradiation. The overall survival curves were similar for both cohorts.

Wolff et al.⁴⁶ examined 86 patients treated with weekly gemcitabine at a dose of 400 mg/m² and 30 Gy of radiation. Sixty-one patients ultimately underwent resection (71%). The median survival in the resected patients was 36 months which is significantly longer than those seen in regimens using 5-FU or paclitaxel as the radiation sensitizer. Analysis of the specimens revealed two pathologic complete responses and more than 50% nonviable tumor cells in 36 (59%). A gemcitabine-based regimen was also used in a multi-institutional study of 20 patients reported by Talamonti et al.⁴⁷ This group used full-dose gemcitabine and limited field radiation to 36 Gy (2.4 Gy/fraction). The authors described 14 patients as resectable and six as borderline resectable. Ultimately, all patients were explored and 17 resected (85%), again representing a very high rate of resectability. A single pathologic complete response was observed and, in 24% of tumors, greater than 90% of the tumor cells were felt to be nonviable. Also notable was the low incidence (6%) of margin positivity in this trial. The median survival in the resected patients was 26 months. Based on the results of these initial trials, gemcitabine-based neoadjuvant regimens remain of considerable interest.

TREATMENT

PALLIATION

7 Unfortunately, it has been the experience nationwide that only a minority of patients with carcinoma of the pancreas can undergo resection for possible cure at the time diagnosis is made. Therefore, the optimal palliation of symptoms to maximize quality of life is of primary importance in most patients with pancreatic cancer. Both operative and nonoperative options are available for the palliation of pancreatic cancer.

Jaundice

Obstructive jaundice is present in most patients who have pancreatic cancer. If left untreated, it can result in progressive liver dysfunction, hepatic failure, and early death. In addition, the pruritus associated with obstructive jaundice can be debilitating and usually does not respond to medication. When patients undergo exploration for possible cure and are found to have unresectable disease, a biliary bypass should be performed.

Traditionally, surgeons have performed either choledochojejunostomy or cholecystojejunostomy for the relief of malignant biliary obstruction. Both procedures are effective in relieving jaundice, but it appears that the rate of recurrent jaundice after cholecystojejunostomy is approximately 10%. Therefore, our preference for the palliation of obstructive jaundice is a hepaticojejunostomy or choledochojejunostomy reconstructed with a Roux-en-Y limb of jejunum. The surgical palliation of jaundice can be accomplished safely, with a mortality rate of less than 3% and an overall morbidity rate of 30% to 40%.⁵⁰ In recent years, nonoperative palliation has become available as an option for managing patients who are deemed unresectable by preop staging. Plastic or metal stents can be placed across the biliary obstruction by either an endoscopic or a percutaneous technique. For pancreatic cancer, the endoscopic approach is usually preferred. The overall morbidity rate for endoscopic stenting ranges up to 35%, but the rate of major procedure-related morbidity is less than 10%. Early complications include cholangitis, pancreatitis, and bile duct or duodenal perforation. The major late complications of stent placement are cholecystitis, duodenal perforation, and stent migration. Stent occlusion can result in episodes of cholangitis and recurrent jaundice. For most patients, an exchange of stents is required every 3 to 6 months. The newer metal stents appear to remain patent for longer periods.

Nonoperative palliation appears to be associated with lower complication rates, lower procedure-related mortality rates, and shorter initial periods of hospitalization in comparison with surgical palliation. However, the rate of recurrent jaundice is higher. No advantage with respect to long-term survival has been noted for either approach. Therefore, nonoperative palliation should be offered to patients with advanced disease or poor performance status. Surgical palliation should be considered for patients with an anticipated life expectancy of at least 6 months.

Duodenal Obstruction

At the time that pancreatic cancer is diagnosed, approximately one-third of patients have symptoms of nausea or vomiting. Although true mechanical obstruction of the duodenum seen by radiologic or endoscopic examination is much less frequent, duodenal obstruction develops in almost 20% of patients before they die as the disease progresses.⁵¹ Duodenal obstruction can be caused in the C-loop by cancers of the head or at the ligament of Trietz by cancers of the body and tail. In patients with evidence of duodenal obstruction or impending obstruction, a gastrojejunostomy is indicated for palliation. This is typically performed as a retrocolic, isoperistaltic loop gastrojejunostomy with a loop of jejunum 20 to 30 cm distal to the ligament of Trietz.

In patients with unresectable pancreatic cancer who do not have symptoms of gastric outlet obstruction, whether or not to perform a prophylactic gastric bypass at the time of biliary bypass is a

matter of debate. Surgeons who do not perform a prophylactic bypass feel that it needlessly increases the postoperative length of stay and can be associated with delayed gastric emptying and increased morbidity and mortality. However, data from a prospective, randomized trial of prophylactic gastrojejunostomy in patients with unresectable cancer do not support this view.⁵² In this study, 44 patients were randomized to a gastrojejunostomy, and 43 did not undergo gastric bypass. No mortality occurred in either group. No difference was observed in either the complication rate or the postoperative length of stay (Table 55-16). However, late duodenal obstruction developed in 19% of the patients who did not undergo bypass. A recent multicenter prospective randomized controlled trial has confirmed these results.⁵³ Therefore, we believe that a prophylactic gastrojejunostomy should be performed in patients undergoing surgical palliation for unresectable pancreatic carcinoma.

Pain

Tumor-associated pain can be incapacitating in patients with unresectable pancreatic cancer. The postulated causes of tumor-associated pain are many and include tumor infiltration into the celiac plexus, increased parenchymal pressure caused by pancreatic duct obstruction, pancreatic inflammation, gallbladder distention resulting from biliary obstruction, and gastroduodenal obstruction. The management of pain in patients dying of carcinoma of the pancreas is one of the most important aspects of their care. The appropriate use of oral agents can be successful in most patients. Patients with significant pain should receive their medication on a regular schedule and not on an “as-needed” basis. The use of long-acting morphine derivative compounds appears to be best suited for such treatment. Percutaneous neurolytic block of the celiac axis, performed under either fluoroscopic or CT guidance, is also successful in the majority of patients at eliminating pain. Patients with unresectable cancer at the time of surgical exploration should receive a chemical splanchnicectomy, with 20 mL of 50% alcohol injected on either side of the aorta at the level of the celiac axis.⁵⁴

MANAGEMENT
Table 55-16 Prospective Randomized Trial of Prophylactic Gastrojejunostomy in Patients with Unresectable Periampullary Cancer

	Patients (No.)	Morbidity (%)	Mortality (%)	Postoperative Length of Stay (Days)	Late Gastric Outlet Obstruction (%)
Gastrojejunostomy	44	32	0	8.5	0
No gastrojejunostomy	43	33	0	8.0	19

Adapted from Lillemoe KD, Cameron JL, Hardacre JM, et al. Is prophylactic gastrojejunostomy indicated for unresectable periampullary cancer? *Ann Surg* 1999;230:322–330.

SUMMARY

8 The decision to perform nonoperative versus surgical palliation for pancreatic cancer is influenced by a number of factors, including the patient’s symptoms, overall health status, predicted procedure-related morbidity and mortality, and projected survival. Surgical palliation can be completed with acceptable perioperative morbidity and mortality and postoperative length of stay. The avoidance of late complications of recurrent jaundice, duodenal obstruction, and disabling pain would strengthen the argument in favor of surgical palliation in those patients expected to survive 6 months or more. Nonoperative methods of palliation should be considered for patients in whom preoperative staging suggests distant metastatic disease or a locally unresectable tumor, patients who are not candidates for operative intervention, and those not expected to survive more than 3 months.

Radiation and Chemotherapy for Unresectable Pancreatic Carcinoma

Specific antitumor therapies in patients with advanced pancreatic carcinoma have been studied for years, with limited success. Trials evaluating the use of chemotherapy and radiation therapy both alone and in combination have shown a marginal improvement in survival, often with relatively high toxicity rates and some negative impact on quality of life. Recently gemcitabine, a deoxycytidine analog capable of inhibiting DNA replication and repair, has become increasingly popular. When gemcitabine was compared with bolus 5-FU in a randomized phase III trial, it was shown to confer a significant survival benefit in advanced pancreatic cancer, increasing median survival from 4.4 to 5.7 months and increasing 1-year survival from 2% to 18%, respectively.⁵⁵ A key end-point in this study was “clinical benefit

response,” based on reducing pain, improving performance status, and inducing weight gain, which was attained in 24% of patients receiving gemcitabine compared with 5% for those receiving 5-FU. In patients with metastatic pancreatic cancer that had progressed with 5-FU and then been treated with gemcitabine, the median survival (in 63 of 74 patients enrolled) was 3.9 months.⁵⁶ Seventeen patients (27%) attained a clinical benefit response with a median duration of 14 weeks. Gemcitabine is generally well tolerated with a low incidence of significant toxicity and therefore seems to be a reasonable choice for palliative therapy.

Long before gemcitabine was established as an option for adjuvant therapy, it was approved in the metastatic setting based on clinical benefit in patients who had symptomatic advanced disease.⁵⁵ Over the last two decades, several combinations of gemcitabine based chemotherapy have failed to improve outcome in patients with metastatic disease. Recently, both FOLFIRINOX (5-FU, leucovorin, irinotecan, and oxaliplatin) and nab-paclitaxel/gemcitabine were proven superior to gemcitabine alone in patients with metastatic pancreatic cancer leading to improvement in response rate (RR), progression-free survival (PFS) and OS.^{57,58} Objective response rates have improved by nearly fivefold with these newer systemic regimens.

In addition to gemcitabine, other agents are currently being studied for a role in the palliation of patients with pancreatic adenocarcinoma. Examples of such agents are paclitaxel (Taxol), matrix metalloproteinase inhibitors (e.g., marimastat and perillyl alcohol), and inhibitors of angiogenesis, such as TNP-470. The results of such studies are eagerly awaited.

Chapter 56

Neoplasms of the Endocrine Pancreas

Harish Lavu, Jonathan R. Brody, and Charles J. Yeo

Key Points

- 1 Pancreatic endocrine neoplasms (PENs) originate from multipotential stem cells in pancreatic ductules. Therefore, use of the older terms *islet cell tumor* and *islet cell carcinoma* is now discouraged, in favor of the terms *pancreatic endocrine neoplasms* or *pancreatic endocrine tumors*.
 - 2 PENs have traditionally been classified according to the size and the mitotic rate of the tumor into one of three categories: pancreatic endocrine microadenomas, well-differentiated PENs, and poorly differentiated or high-grade endocrine carcinomas.
 - 3 The most recent World Health Organization classification uses the combination of a proliferative index (Ki-67) and mitotic rate to grade PENs while incorporating traditional TNM staging taking into account tumor size, peripancreatic invasion, and metastatic spread to lymph nodes/distant locations, which result in the classification of carcinoma.
 - 4 The best initial imaging technique for a PEN is a high-quality multidetector computed tomography (CT) scan.
 - 5 Endoscopic ultrasonography is particularly useful in localizing tumors in patients with gastrinoma and insulinoma.
 - 6 Insulinomas may present with either neuroglycopenic symptoms (confusion, seizure, obtundation, and coma) or hypoglycemic-induced symptoms (palpitations, diaphoresis, and tachycardia).
 - 7 Ninety percent of insulinomas are solitary, 90% are sporadic, and 90% are benign with their location evenly distributed throughout the pancreas.
 - 8 Seventy-five percent of gastrinomas are sporadic (25% are associated with multiple endocrine neoplasia type 1 syndrome), and all should be considered to be of malignant potential.
 - 9 Most gastrinomas are located in the *gastrinoma triangle* and may be intrapancreatic, within the wall of the duodenum, or in a peripancreatic lymph node, and in most cases local resection (enucleation) may be adequate therapy.
 - 10 Glucagonomas usually present with a characteristic severe dermatitis (termed *necrolytic migratory erythema*) and are typically large and bulky and often with metastatic disease.
-

1 Pancreatic endocrine neoplasms (PENs) are rare tumors that account for 3% of pancreatic neoplasms and 7% of all neuroendocrine tumors.¹ Their incidence has increased nearly fivefold over the past 30 years, corresponding to the dramatic rise in the use of cross-sectional imaging in modern medicine. This has led to an increase in the rate of incidental diagnoses in asymptomatic patients.² First described by Nicholls in 1902 as a tumor arising from pancreatic islet cells, these “islet cell adenomas” were long thought to arise from the islets of Langerhans.³ Recent investigations have revealed that PENs more likely originate from multipotential stem cells in pancreatic ductules.^{4,5} This non-islet cell origin has been further demonstrated in tumors arising in patients with multiple endocrine neoplasia type 1.⁶ Therefore, use of the older terms *islet cell tumor* and *islet cell carcinoma* is now discouraged, in favor of the terms *pancreatic endocrine neoplasms* or *pancreatic endocrine tumors*.^{7,8}

2 Traditionally, PENs were classified according to their size and the mitotic rate of the tumor. This system placed PENs into one of three categories: pancreatic endocrine microadenomas, well-differentiated PENs, and poorly differentiated or high-grade endocrine carcinomas. PENs are also differentiated by the presence (i.e., functional tumors) or absence (i.e., nonfunctional tumors) of a syndrome due to hormone production, with nonfunctional PENs (91%) being much more common than functional tumors (9%).^{9,10} The production of certain hormones by the functional tumors and their resulting symptoms lead to well-described clinical syndromes, which are detailed later in this chapter.

PENs less than 0.5 cm in diameter are classified as pancreatic endocrine microadenomas.

Oncologically, they are considered to be benign lesions. Their prevalence is estimated to be as high as 10% of the population in autopsy series.^{11,12} Most pancreatic endocrine microadenomas are noted as incidental findings in pancreata resected for other indications and, by definition, produce no neoplastic syndromes (i.e., are nonfunctional). Functional PENs less than 0.5 cm are classified with well-differentiated PENs.

PENs measuring greater than 0.5 cm in diameter and having a low mitotic rate of less than 10 mitoses per 10 high-power fields are referred to as well-differentiated PENs. This group comprises the large majority of clinically relevant PENs. They are uncommon, with an estimated incidence of approximately 1 out of 100,000 people.^{13,14} Although rare in children, cases have been described at all ages, and the peak incidence occurs between the ages of 40 and 60 years.⁷ Overall distribution is equal between men and women with some differences in ratio among different functional types.

3 The classification of PENs has in the past been controversial, with no single dominant staging system in existence.¹⁵ Multiple varying staging schemes (including those by the European Neuroendocrine Tumor Society (ENETS) and the American Joint Committee on Cancer (AJCC))^{16,17} have been put forward, attempting to establish prognostic characteristics such as size, mitotic count, presence of necrosis, extrapancreatic invasion, vascular and perineural invasion, nuclear polymorphisms, and nodal involvement.^{18–21} The most recent World Health Organization (WHO) classification attempts to standardize PEN grading by using a proliferation-based system together with classical histopathologic diagnostic criteria. This new classification takes into account the increasing importance of the proliferative index Ki-67 as a prognostic marker for PENs. In this schema, PENs are graded into one of three categories based upon their Ki-67 proliferation index and mitotic rate. These include two categories of well-differentiated endocrine tumors and a third category of poorly differentiated endocrine carcinomas. In this system, the well-differentiated tumors include those which are grade 1 (Ki-67 <3%, <2 mitoses per 10 hpf) and grade 2 (Ki-67 3% to 20%, 2 to 20 mitoses per 10 hpf). Whereas, grade 3 (Ki-67 >20%, >20 mitoses per 10 hpf) tumors are considered poorly differentiated carcinomas.^{22,23} By convention, the tumor is assigned the higher grade if the Ki-67 index and mitotic rate differ. Any local invasion beyond the pancreas or metastatic spread to lymph nodes or distant locations results in the classification of carcinoma (Table 56-1).

Table 56-1 WHO 2010 Classification of Well-Differentiated Pancreatic Endocrine Tumors

Grade	Mitotic Count/10 HPF	Ki-67 Index (%)
G1	<2 per 10 HPF	<3
G2	2–20	3–20
G3	>20	>20
TNM	Size (cm)	Muscularis Propria Invasion
T1a	<1	–
T1b	1–2	–
T2	>2	+

HPF, high-power fields; WHO, World Health Organization.

Well-differentiated PENs can also be classified as functional or nonfunctional based on the presence or absence of an associated clinically recognizable syndrome (Table 56-2). These syndromes are the result of the secretion of biologically active hormones by the tumors and are confirmed by measurable elevations of the hormones in the blood. The most common functional PENs include insulinomas, gastrinomas, vasoactive intestinal polypeptide-omas (VIPomas), glucagonomas, and somatostatinomas. The incidence of these lesions ranges from 1 per 1 million for insulinomas to 1 per 40 million for somatostatinomas.²⁴ Even less common PENs secreting calcitonin,^{25,26} parathyroid hormone–related protein,²⁷ growth hormone–releasing factor, and adrenocorticotrophic hormone²⁸ have been reported. Nonfunctional PENs are classified as such due to their lack of an associated clinical syndrome. Some of the tumors in this group do secrete elevated amounts of hormones, including chromogranin A, which can be detected in either the serum or in surgical specimens using immunohistochemistry.²⁹ These secreted hormones either produce no clinical syndromes, as is seen with tumors that secrete pancreatic polypeptide,³⁰ or secrete hormones in subclinical amounts or inactive forms. Traditionally, functional PENs were reported to comprise the majority of PENs. As methods of detecting these lesions and patterns of presentation have evolved, due primarily to the widespread use of high-quality cross-

sectional imaging, nonfunctional PENs now comprise the vast majority of surgically resected cases.^{18,31}

The least common group of PENs is the poorly differentiated or high-grade endocrine carcinomas. These are aggressive tumors characterized by their high mitotic count and proliferation index (>20 mitotic figures per 10 high-powered fields, Ki-67 >20%).^{23,32} These tumors primarily occur in adults and have a male predominance. Some have been reported to be functional, producing varied clinical syndromes (commonly gastrinoma, VIPoma, glucagonoma, and, less frequently, insulinoma). Prognosis is often poor, with the clinical course varying from a rapid decline to a more indolent, prolonged survival.

Table 56-2 Classification of Functional Pancreatic Endocrine Tumors

Tumor (Syndrome)	Clinical Features	Extrapancreatic Location	Malignancy Rate
Insulinoma	Hypoglycemia Anabolic state	Rare	10%
Gastrinoma (Zollinger–Ellison)	Peptic ulcer Diarrhea	Frequent	50%
VIPoma (Verner–Morrison; WDHA; pancreatic cholera)	Watery diarrhea Hypokalemia Achlorhydria/acidosis	10%	Most
Glucagonoma	Hyperglycemia Catabolic state Dermatitis	Rare	Most
Somatostatinoma	Hyperglycemia Steatorrhea Gallstones	Rare	Most

WDHA, watery diarrhea, hypokalemia, and either achlorhydria or acidosis.

MOLECULAR GENETICS

The majority of PENs are sporadic. Some of them, however, occur as part of inherited familial syndromes such as multiple endocrine neoplasia type 1 (MEN-1), von Hippel–Lindau (VHL) syndrome, neurofibromatosis (NF-1), and tuberous sclerosis (TSC) (see section below on genetic syndromes) (Table 56-3). Recent advances in high throughput DNA sequencing techniques have provided new insights into the genesis of PENs and possible reasons why certain tumors behave more aggressively than others as well as why tumors may respond more favorable to specific therapies (i.e., a more personalized approach to therapy of PENs).

Whole-Exome Sequencing of PENs

Specifically, in a 2011 landmark paper, Jiao et al. sequenced ~18,000 coding genes of 10 clinically well-characterized PENs.³³ Technically, this work dovetailed eloquently and aligned with the group’s previous work of sequencing and analyzing multiple pancreatic ductal adenocarcinoma genomes.³⁴ Importantly, the investigators microdissected the samples in an effort to achieve a high purity and quality of DNA from neoplastic tissue. In the PENs cancer genomes compared to pancreatic ductal adenocarcinoma genomes a number of differences were discovered including >50% fewer mutations in PENs compared to pancreatic adenocarcinoma genomes; and commonly mutated genes such *KRAS* were not mutated in PENs (Table 56-4).³⁵ These genetic data support the notion that the chromosomal instability (CIN) and tumorigenesis process between these two pathologically distant pancreatic neoplasms are initiated by unique molecular and/or environmental events. The study went on to validate the common findings in the 10 PENs (labeled a discovery set) with an additional 58 PENs. Validating previous work and also underscoring the importance of the disruption in the chromatin-remodeling pathway in PENS, a majority of PENs harbored a tumor-specific inactivating mutation in *MEN-1*. Additional genes functionally important in a chromatin-remodeling complex, *DAXX* (death-domain–associated protein) and *ATRX* (alpha thalassemia/mental retardation syndrome X-linked), were frequently mutated in PENs as well. Correlating the clinical outcomes of these tumors, the study demonstrated that patients in this cohort with *MEN-1*, *DAXX*, and *ATRX* mutated tumors had unique outcomes compared to the other PENs. More recent work published in 2014, correlated *DAXX* and *ATRX* mutations, activation of alternative lengthening of telomeres, and global chromosomal alterations with pathologic features and outcome data.³⁶ Interestingly, this study identified that PENs harboring *DAXX*

and *ATRX* mutations were more likely to have CIN and patients with this subtype of PENs had a reduction in survival.

Table 56-3 Familial Genetic Syndromes Associated with Pancreatic Endocrine Neoplasms (PENs)

Syndrome	Chromosomal Location	Gene Product	PEN Type
MEN-1	11q13	Menin	Gastrinoma Nonfunctional
VHL syndrome	3p25–26	VHL gene	Various
NF-1	17q11.2	Neurofibromin	Somatostatinomas

MEN-1, multiple endocrine neoplasia 1; NF, neurofibromatosis; VHL, von Hippel–Lindau.

This landmark sequencing work underscored the potential clinical importance of mutations in the mTOR pathway in a subset of PEN patients. As a reminder, the drug rapamycin targets mTOR, and thus, this finding should provide the framework in which we may stratify PEN patients for TOR inhibitor-based therapies (e.g., everolimus).³³ As this work demonstrated that mTOR dysregulation may be an important predictive marker, others have shown that in a large panel of neuroendocrine tumors (195 of which only 19 were pancreatic) mTOR overexpression and/or its downstream-activated targets were associated with worse clinical outcomes (i.e., adverse prognostic markers).³⁷ This work provides another instance where a poor prognostic marker (for even development of disease) may serve counterintuitively as a positive predictive marker (for everolimus); an established biomarker, *BRCA2*, acts in a similar fashion.

Table 56-4 Portal Vein Sampling

Target Pathway	PDAC	PENs
Kras	>90%	0%
mTOR	<1%	~15%
TP53	>80%	<5%
DAXX/ATRX	0%	>40%
MEN1	0%	>40%

Examples of discovered “potential targeted” pathways/genes in pancreatic ductal adenocarcinoma (PDAC) compared to PENs. The percent roughly estimates the number of PDACs and PENs that would benefit from these potential targeted approaches.³⁵

Genetic Links and Syndromes Related to PENs

Significant progress has been made in the genetic understanding of the MEN-1 syndrome in relation to PENs.³⁸ Chromosomal linkage studies have localized the genetic defect to the 11q13 locus, and studies of DNA markers have localized the MEN-1 gene between PYGM and D11S97. The gene contains 10 exons that code for a 610-amino-acid protein called menin, whose function is unknown, although it is classically labeled as a tumor suppressor gene. Some studies provide a possible explanation for loss of this gene in neuroendocrine tumors.³⁹ The menin protein is expressed in diverse tissues and is highly conserved evolutionarily. Menin is predominately a nuclear protein, which binds to JunD and may repress JunD-mediated transcription. Studies in patients with MEN-1 have shown allelic deletions at chromosome 11q13 in nearly 100% of parathyroid tumors, 85% of nongastrinoma islet cell tumors, and up to 40% of gastrinomas. In patients with sporadic tumors (without MEN-1), 11q13 deletions are seen in about 25%, 20%, and almost 50% of parathyroid tumors, nongastrinoma PENs, and gastrinomas, respectively. Recently it has been shown that a comprehensive genetic testing program for patients at risk for MEN-1 can identify patients harboring a MEN-1 mutation almost 10 years before the development of clinical signs or symptoms of disease.⁴⁰ Since MEN-1 loss has been detected in both the sporadic and the familial forms of PENs, the menin pathway is most likely involved in the overall pathogenesis of this disease, whether familial or sporadic in nature.³⁹

Less frequently than MEN-1, PENs may be associated with VHL syndrome. VHL syndrome is another autosomal dominant inheritance disease that includes many clinical disorders⁴¹ including retinal hemangioblastomas, cerebellar and medullary hemangioblastomas, and PENs. PENs are found in a small percentage of patients with VHL syndrome. A mutation in the VHL gene, a tumor suppressor located on chromosome 3p25–26, which regulates hypoxia-induced cell proliferation, is responsible. Although

germline mutations with loss of heterozygosity (LOH) are associated with this disease, it has been proposed that other tumor suppressors most likely cooperate with VHL in order to form PENs. VHL-mutated PENs have been shown to have specific defects in angiogenesis and hypoxia-inducible factor pathways.⁴²

NF-1 (von Recklinghausen disease) is an autosomal dominant disorder that produces a well-described clinical syndrome characterized by café-au-lait spots and neurofibromas. These patients may develop pancreatic somatostatinomas, often near the ampulla of Vater. The NF-1 gene is a tumor suppressor gene located on 17q11.2 that encodes for neurofibromin, a regulator of the mammalian target of rapamycin (mTOR) pathway. Loss of NF-1 results in mTOR activation and tumor development.^{43,44}

Complementary Progression Modeling

Based on the data from the Marinoni study that attempted to molecularly subtype PENs,³⁶ a stepwise progression model of PENs were put forth: (1) initiation occurs (unknown mechanism); (2) DAXX/ATRX mutations induce transformation; (3) alternative lengthening of telomere (ALT)⁴⁵ activation and CIN; (4) clonal heterogeneity and a selection of clones; and (5) metastases.³⁶ Complementary to this work, Zhang described a “double hit model” of PEN progression³⁵ wherein a first mutational hit (e.g., MEN1 or p53) can induce cell cycle progression, even under harsh tumor microenvironment conditions (low glucose). Then, the second hit (ATRX and mTOR) can cause cell growth and enhance cell invasion and metastatic potential,³⁵ even in the absence of cell–cell adhesion. These models highlight our recent and enhanced knowledge of the molecular etiology of PEN. However, future work will need to define the main initiating event that sets the stage for PEN transformation. Since *KRAS* activation appears to be unnecessary, other nonclassical genetic events (e.g., epigenetics and posttranscriptional gene regulation) should be surveyed as critical key events in this tumorigenesis process.

Molecular Targeting of PENs

In summary, PENs are becoming easier to characterize molecularly (and clinically) due to large scale sequencing efforts and a better understanding behind the molecular biologic aspects of these pancreatic tumors. Ongoing efforts to search for candidate genes and novel pathways that set the stage for CIN and initiation of tumorigenesis in these tumors will aid in unraveling the molecular etiology of this disease and perhaps even better druggable targets (see [Table 56-4](#) for molecular pathways to target in PENs vs. pancreatic ductal adenocarcinoma). Still, the molecular characterization of these tumors have helped to pave the way for clinical trials targeting tyrosine kinases (e.g., sunitinib) and the mTOR pathways (e.g., everolimus). In fact, recent work explored targeting multiple points throughout the dysregulated pathway (PI3K/AKT/mTOR) in PENs by combining PI3K inhibitors with mTOR inhibitors and demonstrated that this combination may break initial and acquired drug resistance in PENs.⁴⁶ Future molecular interrogation of PENs combined with these types of preclinical targeting approaches should continue to move the field closer to a personalized approach to treating PENs with better targeted therapies.

PRESENTATION AND EVALUATION

There are three primary ways by which patients with PENs come to clinical attention: the incidental discovery of a mass in the pancreas during cross-sectional imaging, symptoms secondary to the mass effect of a lesion in the pancreas (i.e., obstructive jaundice or pain), and, as a consequence of the symptoms of a syndrome associated with a functional PEN. As mentioned previously, incidentally detected nonfunctional PENs currently comprise the majority of clinically relevant tumors. They are typically hypervascular on imaging studies such as computed tomography (CT) or magnetic resonance imaging (MRI). In the absence of any clinical syndrome, these lesions can be managed as any other incidental pancreatic lesion. Typically, the size of a PEN at discovery guides decision making between three standard options: serial observation, endoscopic ultrasound-guided biopsy, or definitive surgical resection. Size greater than 2 cm is a standard stratification measure, with lesions larger than this usually managed in a more aggressive fashion. If a nonfunctional PEN is suspected, baseline serum levels of chromogranin A and pancreatic polypeptide can be useful diagnostic markers prior to surgical resection. Chromogranin A is a 49-kDa protein contained within the neurosecretory vesicles of PENs, whose levels should be measured prior to surgical resection and are expected to significantly decline in the postoperative period with removal of the tumor burden. The chromogranin A levels can be tracked over time to document tumor recurrence, often before the lesions become visible on cross-sectional

imaging studies.⁴⁷ Pancreatic polypeptide is secreted by the PP cells of the islets of Langerhans and can also be used to track patients with PENs, though its sensitivity (63%) is lower than that of chromogranin A.⁴⁸ Neuron-specific enolase is another tumor marker that is elevated in approximately 50% of PENs, most commonly in patients with pulmonary metastases.⁴⁹

PENs presenting due to mass effect on surrounding structures resulting in jaundice, pain, or gastric outlet obstruction are uncommon. These lesions should be addressed as any other symptomatic pancreatic lesion with definitive surgical resection if clinically appropriate.

Patients presenting with symptoms from a functional PEN can be a diagnostic challenge. Three general principles apply to the diagnosis and treatment of patients with suspected functional neoplasms of the endocrine pancreas. One must first recognize the abnormal physiology or characteristic syndrome. Patients are often misdiagnosed or have their symptoms disregarded for years before an accurate diagnosis is reached. Characteristic clinical syndromes are well described for insulinoma, gastrinoma, VIPoma, and glucagonoma. The somatostatinoma syndrome is nonspecific, much more difficult to recognize, and exceedingly rare. Second is the detection of hormone elevations in the serum by radioimmunoassay. Such assays are readily available for measuring insulin, gastrin, vasoactive intestinal peptide (VIP), and glucagon. Assays for somatostatin, pancreatic polypeptide (PP), prostaglandins, and other hormonal markers are less commonly available but can be obtained from certain laboratories. The third step involves localizing and staging the tumor in preparation for possible operative intervention ([Algorithm 56-1](#)).

LOCALIZATION AND STAGING

Computed Tomography

4 The initial imaging technique used to localize a PEN and stage the disease is high-quality multidetector three-dimensional CT.⁵⁰ The accuracy of CT in detecting primary PENs ranges from 64% to 82% and depends largely on the size of the tumor.^{51,52} PENs are typically hyperdense (bright) on arterial phases of imaging. Lesions that are obvious during the early arterial phase can become isodense on later phases of imaging. Therefore, a multiphase approach is typically recommended.^{53,54} CT is useful in assessing size and location of the primary tumor, proximity to visceral vessels, peripancreatic lymph node involvement, and the presence or absence of liver metastases ([Fig. 56-1](#)).

Magnetic Resonance Imaging

MRI is increasingly used in the detection of PENs, particularly small lesions. They are especially well visualized on T1- and T2-weighted images with fat suppression. MRI has the advantage of increased soft tissue contrast without the administration of intravenous contrast when compared to CT.⁴² PENs characteristically have high signal intensity on T2-weighted images.⁵⁵ On dynamic contrast-enhanced T1-weighted images, the tumors show the same typical enhancement pattern as on CT scan. The sensitivity of MRI has been reported to be between 74% and 100%.^{51,52}

Algorithm 56-1. Diagnosis and management of pancreatic endocrine neoplasms.

Somatostatin Receptor Scintigraphy (Octreoscan)

Somatostatin receptor scintigraphy (SRS) also plays an important role in imaging patients with pancreatic endocrine tumors.⁵⁶⁻⁶² In this technique, the octapeptide analog of somatostatin (Octreotide) labeled with indium-111 is administered intravenously to patients in whom a PEN is suspected. Because neuroendocrine tumors often express large numbers of somatostatin receptors on their cell surfaces (Fig. 56-2), the tracer preferentially identifies tumors. The overall sensitivity of SRS has been reported to range from 74% to near 100% depending on the functional type of PEN.⁶³ There is a significant false-negative rate, indicating that negative SRS findings in patients with PENs should be viewed with caution. Nonfunctional tumors and insulinomas seem to be localized less frequently by SRS, while SRS performs well for gastrinoma, VIPoma, and glucagonoma. In addition, SRS appears to play a role in the evaluation of patients with metastatic pancreatic endocrine tumors, especially in identifying extrahepatic tumor spread. In a study by Frilling et al.,⁶² 54% of patients with liver metastases had extrahepatic tumor spread detected by SRS that was not detected by alternate imaging techniques.

Figure 56-1. Computed tomography with oral and intravenous contrast in a patient with biochemical evidence of insulinoma. The neoplasm (*arrow*) is seen as a contrast-enhancing structure, 3 cm in diameter, in the tail of the pancreas posterior to the stomach (S). (From Yeo CJ. Islet cell tumors of the pancreas. In: Niederhuber JE, ed. *Current Therapy in Oncology*. St. Louis, MO: Mosby; 1993:272, with permission.)

Figure 56-2. Octreotide scan (*anterior view*) in a patient with a large endocrine tumor in the tail of the pancreas (large dark mass, upper right) and several hepatic metastases (upper left quadrant). A small amount of the tracer is seen in the bladder (lower midline).

Endoscopic Ultrasound

5 Endoscopic ultrasonography (EUS) has also shown utility in localizing PENs.⁶⁴⁻⁶⁸ Rosch et al.⁶⁷ were able to localize 32 of 39 tumors (82%) correctly with EUS after CT had failed to locate the tumor (Fig. 56-3). In their experience, EUS was more sensitive than the combination of CT and visceral angiography. A more recent study by Proye et al.⁶⁹ evaluated preoperative EUS and SRS in 41 patients with insulinoma and gastrinoma. The sensitivity and positive predictive value of EUS were 77% and 94%, respectively, for pancreatic tumors; 40% and 100%, respectively, for duodenal gastrinomas; and 58% and 78%, respectively, for metastatic lymph nodes. These results indicate that EUS is best at detecting lesions in the head of the pancreas. It is less successful at evaluating the distal pancreas and the duodenal wall. Additionally, the procedure is operator dependent.⁷⁰ These results have been duplicated by others and have led some to suggest that EUS should serve as the initial localization procedure in patients with insulinoma and gastrinoma. Of note, the drawback to EUS is that it does not evaluate accurately for hepatic metastatic disease; rather, it is more sensitive than CT for imaging the duodenal wall, pancreatic parenchyma, and peripancreatic lymph nodes.

Intraoperative Ultrasound

Historically, the primary methods of localizing PENs intraoperatively have been visualization and palpation. With the advent of laparoscopic exploration for PENs, intraoperative ultrasound has been substituted for palpation. Results have been promising, with sensitivities reported between 75% and 90%.^{71,72}

Figure 56-3. Endoscopic ultrasonographic image from a patient with an insulinoma (*arrows*) in the body of the pancreas. SV, splenic vein. (From Rosch T, Lightdale CJ, Botet JF, et al. Localization of pancreatic endocrine tumors by endoscopic ultrasonography. *N Engl J Med* 1992;326:1721-1726, with permission.)

Figure 56-4. Schematic depiction of data from percutaneous transhepatic portal venous sampling (PTPVS) in a patient with an insulinoma. Insulin levels are given in microunits per milliliter. These data localize the neoplasm to the head of the pancreas. (Adapted from Norton JA, Sigel B, Baker AR, et al. Localization of an occult insulinoma by intraoperative ultrasonography. *Surgery* 1985;97:381–384.)

Venous Sampling

Percutaneous transhepatic portal venous sampling (PTPVS) and arterial stimulation with venous sampling (ASVS) are two techniques that are used exclusively for the diagnosis and localization of PENs. In a small number of cases, CT, MRI, SRS, and EUS are unsuccessful at localizing a PEN. When insulinoma or gastrinoma are suspected, PTPVS may help in localizing the occult neoplasm.^{73–77} The technique involves placing a catheter percutaneously through the liver into the portal vein and then sequentially sampling for hormone levels in the splenic vein, superior mesenteric vein, and portal vein, thereby regionalizing the location of hormone production (Fig. 56-4). The overall accuracy of this test ranges from 70% to greater than 95% depending on the number of samples obtained, the persistence of autonomous hormone production by the tumor, and the careful handling and assaying of all samples. ASVS involves the selective visceral arterial injection of secretin or calcium with concurrent hepatic venous sampling for either gastrin or insulin.^{78,79} Gastrinoma cells are known to respond to secretin by releasing gastrin,^{80,81} and insulinoma cells are known to respond to calcium by releasing insulin. The provocative secretagogue is serially injected through an arterial catheter into at least three sites – the splenic, gastroduodenal, and inferior pancreaticoduodenal arteries. Samples are drawn from a hepatic vein catheter before and immediately after each injection. The arterial supply to the occult tumor can then be deduced based on which selective secretagogue injection is followed by a large increase in hepatic vein hormone concentration (Fig. 56-5). This technique, particularly when combined with intraoperative ultrasonography, results in a sensitivity of greater than 90%, essentially obviating the need for blind resection in unlocalized insulinomas.^{71,82} Additionally, ASVS can differentiate the 5% of patients with nesidioblastosis from those with insulinoma.⁸³

SURGICAL EXPLORATION

At the time of surgical exploration for PEN, a complete evaluation of the pancreas and peripancreatic regions is performed. The body and tail of the pancreas are exposed by dividing the gastrocolic ligament and entering the lesser sac. This portion of the pancreas can be partially elevated out of the retroperitoneum by dividing the inferior retroperitoneal attachments to the gland. After the second portion of the duodenum has been elevated out of the retroperitoneum by means of the Kocher maneuver, the pancreatic head and uncinate process are palpated bimanually. The liver is carefully assessed for evidence of metastatic disease. Potential extrapancreatic sites of tumor are evaluated in all cases, with particular attention paid to the duodenum, splenic hilum, small intestine and its mesentery, peripancreatic lymph nodes, and reproductive tract in women. The goals of surgical therapy for PENs include controlling the symptoms of hormone excess, safely resecting maximal tumor mass, and preserving maximal pancreatic parenchyma. Management strategies, including preoperative, intraoperative, and postoperative considerations, vary for the different types of endocrine neoplasms of the pancreas.

Figure 56-5. Graphic depiction of the results of arterial stimulation with venous sampling (ASVS) in a patient with gastrinoma. The rise in hepatic vein gastrin concentration (gastrin gradient) is plotted on the y-axis, and basal values are plotted on the x-axis: 1, 100% rise; 2, 200% rise; and so forth. A rise in the hepatic vein gastrin concentration observed after the injection of secretin into the superior mesenteric artery (SMA) and gastroduodenal artery (GDA) localizes the neoplasm to the head of the pancreas or duodenum. SPL, splenic artery. (Adapted from Thom AK, Norton JA, Doppman JL, et al. Prospective study of the use of intra-arterial secretin injection and portal venous sampling to localize duodenal gastrinomas. *Surgery* 1992;112:1002–1028; discussion 1008–1009.)

INSULINOMA

Insulinoma is the most common functional neoplasm of the endocrine pancreas (Table 56-5). The insulinoma syndrome is associated with the following features, known as Whipple triad⁸⁴:

1. Symptoms of hypoglycemia during fasting
2. Documentation of hypoglycemia, with a serum glucose level typically below 50 mg/dL
3. Relief of hypoglycemic symptoms following administration of exogenous glucose

6 Autonomous insulin secretion in insulinomas leads to spontaneous hypoglycemia, with symptoms that can be classified into two groups (Table 56-5). Neuroglycopenic symptoms include confusion, seizure, obtundation, personality change, and coma. Hypoglycemia-induced symptoms, related to a surge in catecholamine levels, include palpitations, trembling, diaphoresis, and tachycardia. In most cases, patients consume carbohydrate-rich meals and snacks to relieve or prevent these symptoms.

Table 56-5 Insulinoma

Parameter	Description
Symptoms	Neuroglycopenia causes confusion, personality change, coma Catecholamine surge causes trembling, diaphoresis, tachycardia Anabolic state: weight gain
Diagnostic tests	Monitored fast Insulin-to-glucose ratio
Anatomic localization	Evenly distributed throughout pancreas

Whipple triad is not specific for insulinoma. The differential diagnosis of adult hypoglycemia is extensive and includes the following: reactive hypoglycemia, functional hypoglycemia associated with gastrectomy or gastroenterostomy, nonpancreatic tumors, pleural mesothelioma, sarcoma, adrenal carcinoma, hepatocellular carcinoma, carcinoid, hypopituitarism, chronic adrenal insufficiency, extensive hepatic insufficiency, and surreptitious self-administration of insulin or ingestion of oral hypoglycemic agents.

A common error made in evaluating a patient with suspected insulinoma is to begin with an oral glucose tolerance test. Instead, insulinoma is most reliably diagnosed by means of a monitored fast (via

the withholding of exogenous glucose). During a monitored fast, blood is sampled for glucose and insulin determinations every 4 to 6 hours and when symptoms appear. Hypoglycemic symptoms typically occur when glucose levels are below 50 mg/dL, with concurrent serum insulin levels often exceeding 25 microunits/mL. Additional support for the diagnosis of insulinoma comes from the calculation of the insulin-to-glucose ratio at different times during the monitored fast. Normal persons have insulin-to-glucose ratios below 0.3, whereas patients with insulinoma typically demonstrate insulin-to-glucose ratios above 0.4 after a prolonged fast. Other measurable β -cell products synthesized in excess in patients with insulinoma include C peptide and proinsulin. Elevated levels of both are typically found in the peripheral blood of patients with insulinoma.

The possibility of the surreptitious administration of insulin or oral hypoglycemic agents should be considered in all patients with suspected insulinoma. Levels of C peptide and proinsulin are not elevated in patients who self-administer insulin. Additionally, patients self-administering either bovine or porcine insulin may demonstrate anti-insulin antibodies in circulating blood. The ingestion of oral hypoglycemic agents, such as sulfonylureas, can be assessed by means of standard toxicologic screening.

7 Insulinomas are evenly distributed throughout the pancreas, with one-third found in the head and uncinate process, one-third in the body, and one-third in the tail of the gland.⁸⁵ Less than 3% are located outside the pancreas, with these lesions located in the peripancreatic area.⁸⁶ Ninety percent are found to be benign solitary adenomas amenable to surgical cure. Ninety percent of insulinomas are sporadic, with approximately 10% being associated with the MEN-1 syndrome. In patients with MEN-1, the possibility of multiple insulinomas must be considered, and recurrence rates are higher. In approximately 10% of patients, insulinoma is metastatic to the peripancreatic lymph nodes or liver, making the diagnosis of malignant insulinoma.

Figure 56-6. The technique for enucleating a benign pancreatic endocrine neoplasm with scissors (A) or electrocautery (B). C: After enucleation, the site of excision is drained.

After the diagnosis of insulinoma has been confirmed biochemically, the appropriate localization and staging studies described earlier are performed (typically CT and EUS). Once the lesion has been localized,⁸⁷ patients undergo surgical exploration, where the pancreas is assessed not only by operative palpation but also by intraoperative ultrasonography. This allows for confirmation of preoperative localization and evaluates for the presence or absence of multiple primary tumors. Small, benign tumors that are not close to the main pancreatic duct can be removed by enucleation⁸⁸ (Fig. 56-6), regardless of their location in the gland. Larger tumors in the neck or proximal body may be resected via central pancreatectomy.⁸⁹⁻⁹¹ In the body and tail of the pancreas, insulinomas more than 2 cm in diameter and those close to the pancreatic duct are most commonly removed via distal pancreatectomy. Large lesions in the head or uncinate process of the gland may not be amenable to local resection and may occasionally require pancreaticoduodenectomy for complete excision.^{92,93} Increasingly, experienced surgeons are utilizing a laparoscopic approach to these tumors. Both laparoscopic pancreatectomy and

enucleation are now performed on a routine basis with excellent results.^{94–98}

In rare instances, preoperative localization studies and intraoperative ultrasound fail to identify the tumor. Intraoperative biopsy of the pancreatic tail may help make the diagnosis of nesidioblastosis as the cause of hyperinsulism. Some authors have recommended a “blind” distal pancreatic resection to the level of the superior mesenteric vein (60% to 70% pancreatectomy), in the hope of excising an unidentified insulinoma in the body and tail. Others have suggested blind pancreaticoduodenectomy, because the thickness of the gland in this region makes it more likely to harbor an occult neoplasm. The favored approach at the current time is to defer any blind resection, close the patient without pancreatectomy, and perform postoperative selective arterial calcium stimulation with hepatic venous insulin sampling to allow for specific tumor localization and directed surgical excision at a second operation.⁹⁹

Approximately 10% of insulinomas are malignant, presenting with lymph node or liver metastases. In the presence of hepatic metastases, resection of the primary tumor and accessible metastases should be considered if it can be performed safely.^{100–102} Such tumor debulking can be helpful in reducing hypoglycemic symptoms and improving long-term survival. In patients with unresectable disease, medications such as diazoxide and octreotide can be used to reduce insulin secretion from the tumor, minimizing hypoglycemia. One promising new treatment is everolimus, an oral rapamycin analog that inhibits mammalian target of rapamycin (mTOR). In a pilot study of patients with refractory hypoglycemia due to metastatic insulinoma, everolimus resulted in improved glycemic control.¹⁰³ Dietary manipulations, including judicious spacing of carbohydrate-rich meals and the consumption of nighttime snacks, can also reduce the number of hypoglycemic episodes. Multiple chemotherapeutic regimens have been used including streptozocin, dacarbazine, doxorubicin, and 5-fluorouracil.^{104–106} Combination chemotherapy has yielded the highest response rates but has not been shown to be curative.

GASTRINOMA (ZOLLINGER–ELLISON SYNDROME)

8 In 1955, Zollinger and Ellison described two patients with severe peptic ulcer disease and pancreatic endocrine tumors and postulated that an ulcerogenic agent originated from the pancreatic tumor.^{107–109} It has been estimated that approximately 1 in 1,000 patients with primary duodenal ulcer disease and 2 in 100 patients with recurrent ulcer after ulcer surgery harbor gastrinomas.¹¹⁰ Seventy-five percent of gastrinomas occur sporadically, and 25% are associated with the MEN-1 syndrome. Historically, the majority of gastrinomas were found to be malignant, with metastatic disease present at the time of initial workup. With increased awareness and screening for hypergastrinemia, the diagnosis of gastrinoma is made earlier and a higher percentage of patients present with benign and potentially curable neoplasms.¹¹¹

Table 56-6 Gastrinoma

Parameter	Description
Symptoms	Peptic ulcer disease Diarrhea Esophagitis
Diagnostic tests	Serum gastrin measurement Gastric acid analysis (or pH testing) Secretin stimulation test
Anatomic localization	Duodenum and head of pancreas (gastrinoma triangle)

The clinical symptoms of patients with gastrinoma are a direct result of increased levels of circulating gastrin (Table 56-6). Abdominal pain and peptic ulceration of the upper gastrointestinal (UGI) tract are seen in up to 90% of patients. Diarrhea is seen in 50% of patients, with 10% having diarrhea as their only symptom. Esophageal symptoms or endoscopic abnormalities resulting from gastroesophageal reflux are seen in up to half of patients. The diagnosis of gastrinoma should be suspected in several clinical settings, including the initial diagnosis of peptic ulcer disease, recurrent ulcer after medical or surgical therapy, postbulbar ulcer, family history of ulcer disease, ulcer with diarrhea, prolonged undiagnosed diarrhea, MEN-1 kindred, nongastrinoma pancreatic endocrine tumors (high association of secondary hormone elevations), and prominent gastric rugal folds on UGI examination. Serum gastrin

levels should be obtained in all of these settings.

In most patients with gastrinoma, the fasting serum gastrin level is greater than 200 pg/mL. Gastrin levels greater than 1,000 pg/mL in the setting of documented hyperacidity and ulcer disease are virtually pathognomonic for gastrinoma. Because hypergastrinemia can occur in other pathophysiologic states (Table 56-7), fasting hypergastrinemia alone is not sufficient for the diagnosis of gastrinoma. Gastric acid analysis (or at least gastric pH testing) is critical in differentiating between ulcerogenic (high levels of acid) and nonulcerogenic (low levels of acid) causes of hypergastrinemia. To obtain an accurate gastric acid analysis, patients must not be taking antisecretory medications including histamine (H₂)-receptor antagonists or proton pump inhibitors (PPIs). The diagnosis of gastrinoma is supported by a basal acid output above 15 mEq/hr in nonoperated patients, a basal acid output exceeding 5 mEq/hr in patients with previous vagotomy or ulcer operations, or a ratio of basal acid output to maximal acid output exceeding 0.6.

Table 56-7 Disease States Associated With Hypergastrinemia

Figure 56-7. Results of intravenous secretin stimulation tests in patients with atrophic gastritis (*triangles*), gastric outlet obstruction (*squares*), and gastrinoma (*circles*). A positive test result, consistent with the presence of gastrinoma, is indicated by an increase over basal serum gastrin levels of at least 200 pg/mL. (Adapted from Wolfe MM, Jensen RT. Zollinger-Ellison syndrome: current concepts in diagnosis and management. *N Engl J Med* 1987;317:1200–1209.)

After documenting that hypergastrinemia and excessive acid secretion exist, provocative testing with secretin should be performed to differentiate between gastrinoma, antral G-cell hyperplasia or hyperfunction, and the other causes of ulcerogenic hypergastrinemia. This is achieved with a secretin stimulation test (Fig. 56-7). A baseline gastrin level is drawn. The patient is then stimulated with 2 units/kg of secretin as an intravenous bolus and subsequent gastrin samples are collected at 5-minute intervals for 30 minutes. An increase in the gastrin level by more than 200 pg/mL above the basal level supports the diagnosis of gastrinoma.

After the biochemical diagnosis of gastrinoma has been made, the gastric acid hypersecretion should be pharmacologically controlled. The PPIs are now considered the drugs of choice for doing so.^{112,113} The dose is adjusted to achieve a nonacidic pH during the hour immediately before the next dose of the drug. Typically, PPI doses needed for acid control exceed usual dosing levels. After the initiation of antisecretory therapy, all patients should undergo imaging studies to localize the primary tumor and to assess for metastatic disease.

If localization studies reveal unresectable hepatic metastases, the patient should undergo percutaneous or laparoscopic-directed liver biopsy to obtain a definitive histologic diagnosis. These patients should be maintained on long-term PPI therapy. Virtually all patients can be rendered achlorhydric with an appropriate dose of PPIs. Patients noncompliant with antisecretory therapy who experience complications related to their ulcer diathesis may require removal of the end organ (total

gastrectomy) if tumor resection is not possible. However, total gastrectomy, once the operation of choice for gastrinoma, is now only rarely used.

9 If unresectable disease is not identified by staging studies, patients should be offered surgical exploration with curative intent. On exploration, the entire abdomen should be assessed for areas of extrapancreatic and extraduodenal gastrinomas. Most gastrinomas are found in the *gastrinoma triangle*^{85,114} (Fig. 56-8), the area to the right of the superior mesenteric vessels, in the head of the pancreas or in the duodenal wall. Both intraoperative ultrasound and intraoperative upper endoscopy may be helpful in tumor localization. Transillumination of the duodenum may help identify small duodenal gastrinomas.^{115,116} Well-encapsulated tumors less than 2 cm in size and distant from the pancreatic duct can be enucleated. Those situated deep in the parenchyma may require partial resection by pancreaticoduodenectomy or distal pancreatectomy. If no pancreatic tumor is identified, a longitudinal duodenotomy should be performed at the level of the second portion of the duodenum in search of duodenal microgastrinomas.^{117,118} Small gastrinomas in the duodenal wall can be locally resected with primary closure of the duodenal defect. The routine use of duodenotomy increases the short- and long-term cure rates in patients with sporadic gastrinoma, because such a duodenotomy allows detection of more duodenal gastrinomas.¹¹⁹ Duodenotomy did not impact the occurrence of hepatic metastases or disease-related mortality. In a small percentage of patients, gastrinoma is found only in peripancreatic lymph nodes, with these lymph nodes harboring the apparent primary tumor. Resection of these apparent lymph node primary gastrinomas has been associated with long-term eugastrinemia and biochemical cure in up to half of cases.¹²⁰ A review from the National Institutes of Health identified likely primary lymph node gastrinomas in 26 of 176 gastrinoma patients (14.7%), with 69% being eugastrinemic at a mean of 10 years after resection.¹²¹

Figure 56-8. Most gastrinomas are found within the gastrinoma triangle.

Occasionally, preoperative localization studies may identify the tumor in the gastrinoma triangle, but at the time of exploration, the tumor is not demonstrable. Several surgical options are available at this point. First, a parietal cell vagotomy has been proposed as a way to reduce antisecretory drug dose requirements in patients on high-dose antisecretory drug therapy but without prior life-threatening complications.¹²² However, this approach leaves behind potentially resectable gastrinoma and has lost favor as an option. A second option is total gastrectomy; however, the availability of PPIs has drastically reduced the need to perform this operation for gastrinoma. It may have a limited role in patients whose tumors cannot be localized, if they cannot or will not take their PPIs. Like parietal cell vagotomy, this leaves tumor behind. A third, controversial option in patients with localization to the gastrinoma triangle is blind pancreaticoduodenectomy. Some argue this should include distal gastrectomy, as duodenal gastrinomas may arise close to the pylorus and be left behind during a pylorus-preserving resection.

Patients with sporadic gastrinomas tend to fare better following resection than those with MEN-1. In a series of 151 patients reported by Norton et al.,¹²³ 123 had sporadic gastrinoma and 28 had MEN-1-associated gastrinoma. Of those with sporadic gastrinoma, 34% were free of disease 10 years following resection. None of the MEN-1 patients were free of disease at 10 years. A more recent review of 195 patients from the same institution demonstrated clear superiority of surgical intervention over other treatment strategies.¹²⁴ The rate of disease-related death was increased 23-fold in the group of patients

treated without surgery. These data provide compelling evidence that patients with sporadic gastrinoma benefit from surgical exploration and complete tumor resection.

The management of gastrinoma in MEN-1 is not as clear. The surgical treatment of hypercalcemia caused by parathyroid hyperplasia should precede any surgery for hypergastrinemia in patients with MEN-1. In these patients, gastrin-secreting tumors are often multicentric and associated with lymph node metastases. Although some groups have favored exploration only when MEN-1 gastrinoma tumors exceed 3 cm, it seems that earlier intervention may be warranted.^{125,126} Unfortunately, more data from an appropriate clinical trial are needed to better define the timing of surgery for MEN-1 gastrinoma.

In the 1950s and 1960s, most gastrinomas were diagnosed late in the course of the disease, when the tumor burden was already significant. At that time, effective medical therapy did not exist, nor did sophisticated radiographic localization and staging techniques. Patients often suffered multiple ulcer complications, required total gastrectomy to control the ulcer diathesis, and typically succumbed to continued tumor growth following gastrectomy. Recent reviews of patients with surgically treated gastrinoma provide room for optimism.^{127–130} Currently, up to 35% of patients who undergo resection with curative intent have been rendered eugastrinemic at follow-up. Cure rates approach 60% to 70% when the extent of disease allows a complete resection.

Most patients with incurable metastatic disease eventually die of tumor growth and dissemination. Multiple modalities have been used to treat such patients. Chemotherapy including streptozocin, 5-fluorouracil, and doxorubicin provides response rates of less than 50%.¹³¹ Hormonal therapy with octreotide may relieve symptoms, reduce hypergastrinemia, and diminish hyperchlorhydria.^{132,133} In patients with hepatic metastases, aggressive resection for debulking,^{134–137} hepatic transplantation,¹³⁸ hepatic artery embolization, and interferon therapy have all been used, with variable results.

VIPOMA (VERNER–MORRISON SYNDROME)

Synonyms for VIPoma include WDHA syndrome (watery diarrhea, hypokalemia, and either achlorhydria or acidosis) and pancreatic cholera syndrome (Table 56-8). Verner and Morrison¹³⁹ characterized this secretory diarrheal syndrome in a 1958 report. Patients characteristically present with intermittent, severe, watery diarrhea averaging up to 5 L/d. Hypokalemia results from fecal loss of large amounts of potassium. Low serum potassium levels lead to lethargy, muscle weakness, and nausea. A metabolic acidosis may be present, due to loss of bicarbonate in the diarrhea. Half of the patients may have hyperglycemia or hypercalcemia, and cutaneous flushing can be observed in a minority. The diagnosis of VIPoma is made after other common causes of diarrhea have been excluded (Table 56-9)¹⁴⁰ and an elevated serum VIP level is documented.

Table 56-8 VIPoma

Parameter	Description
Symptoms	Watery diarrhea Weakness Lethargy Nausea
Diagnostic tests	Hypokalemia Achlorhydria Metabolic acidosis Serum VIP levels elevated
Anatomic localization	Most in body and tail of pancreas, with liver metastases

VIP, vasoactive intestinal peptide.

Table 56-9 Differential Diagnosis of Verner–Morrison Syndrome

Entity	Workup
Villous adenoma	Lower GI endoscopy
Laxative abuse	Stool examination for phenolphthalein
Celiac disease	Fecal fat measurement D-xylose tolerance test Small bowel biopsy
Parasitic and infectious diseases	Stool culture Ovum and parasite analysis <i>Clostridium difficile</i> toxin assay
Inflammatory bowel disease	Lower GI endoscopy Upper GI and small bowel series
Carcinoid syndrome	Urinary 5'-HIAA Upper GI and small bowel series Abdominal CT Serum serotonin measurement
Gastrinoma	Serum gastrin measurement Gastric acid analysis Secretin stimulation test

CT, computed tomography; GI, gastrointestinal; 5'-HIAA, 5'-hydroxyindoleacetic acid.

Figure 56-9. Several computed tomographic images from a patient with a primary vasoactive intestinal polypeptide-oma (VIPoma) in the tail of the pancreas. The tumor is nearly spherical. Its location is posterior to the stomach and adjacent to the spleen.

VIP secretion can be episodic, so repeated fasting levels should be measured if there is a strong clinical suspicion. Preoperative tumor localization is critical, because 10% of patients may have extrapancreatic tumors located in the retroperitoneum or chest. Most tumors are located in the distal pancreas where they are amenable to resection via distal pancreatectomy (Fig. 56-9). In most cases, hepatic metastases accompany the primary tumor. Therapies directed at debulking these metastases such as resection or ablative strategies are appropriate.

Surgical excision is appropriate in nearly all patients with Verner–Morrison syndrome. Prior to surgery, fluid and electrolyte imbalances must be corrected. Octreotide can serve as a treatment adjunct, reducing the levels of circulating VIP, with a resultant decrease in the volume of diarrhea. Octreotide is also useful for symptom control in the setting of unresectable disease. Chemotherapy specific for this disease has not been well studied.

GLUCAGONOMA

10 The most common findings in the glucagonoma syndrome are severe dermatitis, mild diabetes, stomatitis, anemia, and weight loss (Table 56-10). The dermatitis manifests as a characteristic skin rash

termed *necrolytic migratory erythema*. This rash exhibits cyclic migrations, and it has been theorized that the hypoaminoacidemia accompanying glucagonoma is the cause.

Table 56-10 Glucagonoma

Parameter	Description
Symptoms	Dermatitis manifested as necrolytic migratory erythema Stomatitis Catabolic state: weight loss
Diagnostic tests	Hyperglycemia Hypoproteinemia Serum glucagon measurement Serum amino acid profile
Anatomic localization	Most in body and tail of pancreas, with liver metastases

The diagnosis of glucagonoma is suggested by the clinical presentation and biopsy of the skin lesions but is secured by the documentation of high fasting levels of serum glucagon. Most glucagonomas are located in the body and tail of the gland. These tumors are typically large and bulky, and surgical resection requires distal pancreatectomy (Fig. 56-10). Metastases are found in most patients and safe debulking of these should be considered.¹⁴¹ As in patients with VIPoma and insulinoma, octreotide can be useful in controlling the signs and symptoms (hyperglycemia and dermatitis) associated with incurable glucagonoma.

SOMATOSTATINOMA

The somatostatinoma syndrome is the least common of the five generally accepted functional pancreatic endocrine neoplasia syndromes, occurring in less than 1 in 40 million people. The clinical features are nonspecific including steatorrhea, diabetes, hypochlorhydria, and cholelithiasis (Table 56-11). Fasting plasma somatostatin levels of greater than 100 pg/mL can be used to confirm the diagnosis.

Most somatostatinomas are located in the pancreatic head or periampullary region.¹⁴² Tumors are of variable size and are often easily localized. Metastatic disease may be present at the time of diagnosis. Safe resection of the primary tumor (often via pancreaticoduodenectomy) and careful debulking of hepatic metastases are indicated.

Figure 56-10. Computed tomography with oral and intravenous contrast in a patient with a glucagonoma. The large tumor appears to be posterior to the stomach and to the right of the aorta from the viewer’s perspective.

Table 56-11 Somatostatinoma

Parameter	Description
Symptoms	Steatorrhea Right upper quadrant pain
Diagnostic tests	Hyperglycemia Hypochlorhydria Gallstones Serum somatostatin level
Anatomic localization	Most in head or uncinate process of pancreas; often periampullary

NONFUNCTIONAL PANCREATIC ENDOCRINE NEOPLASMS

Currently, the majority of patients with neoplasms of the endocrine pancreas have no defined clinical syndrome and no elevated functional hormone levels. Pancreatic PP and chromogranin A levels may be elevated, though neither is associated with a clinical syndrome. A study by Mutch et al.¹⁴³ determined a relationship between fasting plasma PP levels in patients with MEN-1 and the presence of radiographically detectable pancreatic endocrine tumor. A PP level that is more than three times the age-specific normal value is 95% sensitive and 88% specific for a PEN that can be imaged. The majority of patients with nonfunctional endocrine tumors are asymptomatic, however, those who present with symptoms will typically complain of abdominal pain, weight loss, or jaundice, caused by the space-occupying nature of the mass in the pancreas. Overall, nonfunctional tumors tend to grow more slowly and have a more indolent course than the highly lethal pancreatic ductal adenocarcinoma, yet the 5-year survival rate for PENs after resection remains only 65%, with a 10-year survival of 45%.¹⁰

Patients with operable disease should undergo formal surgical resection for potential cure via pancreaticoduodenectomy or distal pancreatectomy, depending on tumor location. Tumor enucleation, without formal resection may be appropriate for patients with small tumors (<2 cm), significant medical comorbidities, or those documented to have a low proliferative index (Ki-67). Patients with locally advanced disease involving the mesenteric vasculature may be candidates for radical mesenteric vascular resection (Fig. 56-11). With successful treatment, these patients can expect to enjoy a median survival in excess of 5 years.^{144,145}

METASTATIC PANCREATIC ENDOCRINE TUMORS

At least one-third of patients with malignant PENs present with synchronous liver metastases at the time of diagnosis.¹⁴⁶ A subset of these patients remain asymptomatic and experience prolonged survival even without aggressive therapy.¹⁰⁴ However, overall 5-year survival with liver metastases is less than 50%.¹⁴⁷ PENs are one of the few tumors for which a survival advantage for surgical debulking has been shown.^{135,146,148–150} In those selected patients where safe surgical resection of greater than 90% of the tumor burden can be achieved, 5-year survival rates of 60% to 75% have been reported.

Those with unresectable disease to the liver may be candidates for a variety of hepatic directed therapies for locoregional control and symptom palliation. These include hepatic artery embolization, radiofrequency/microwave ablation, and infusional chemotherapy.¹⁵¹ Metastatic PENs have shown partial responses to chemotherapy. In 1992, the results of a trial conducted by the Eastern Cooperative Oncology Group (ECOG) were published.¹⁰⁴ In this study, 105 patients with advanced nonfunctional endocrine tumors were randomly assigned to one of three groups. The lowest response rate (30%) was seen in patients receiving chlorozotocin alone, an intermediate response rate (45%) was seen in patients receiving the combination of streptozotocin plus 5-fluorouracil, and the highest response rate (69%) was noted in patients receiving streptozotocin plus doxorubicin. The last regimen also showed significant survival advantage in comparison with the other two treatments. More recent attempts to replicate these results have been disappointing.¹⁵²

Figure 56-11. Computed tomography of a patient with a large PEN(*) replacing the pancreatic body and tail(*), with splenic vein occlusion, perigastric varices (*blue line*), and tumor thrombus (*red line*) growing into the portal vein. This patient underwent a distal pancreatectomy, splenectomy, and partial portal vein resection with tumor thrombectomy, with complete surgical extirpation of the malignancy.

Somatostatin analogs are another approach to treating metastatic PENs. Results are more favorable in tumors that have high-affinity receptors (gastrinomas, VIPomas, glucagonomas, and some nonfunctional tumors) as compared to insulinomas. Symptomatic improvement occurs in 60% to 90% of patients. However, an objective tumor response is seen in only 5% to 15% of patients, with stabilization of disease in 50% or more of patients.^{153–155} In patients who fail to respond to traditional somatostatin analogs, such as octreotide and lanreotide, the novel multireceptor-targeted somatostatin analog pasireotide has shown the ability to offer symptom reduction, primarily because of its ability to bind to four of the five known somatostatin receptor subtypes.¹⁵⁶

Two new targeted therapies have been approved for use in the setting of advanced metastatic PENs based upon the results of large multicenter phase 3 clinical trials. The first is the agent sunitinib malate (Sutent, Pfizer Inc.), an oral, small molecule, multitargeted tyrosine kinase inhibitor initially approved for the treatment of advanced renal cell carcinoma and refractory gastrointestinal stromal tumors. It has activity against VEGF and PDGF. In a large (171 patients) multinational, randomized, double-blind, placebo-controlled phase 3 trial in patients with advanced, well-differentiated PENs, patients receiving sunitinib had a median progression-free survival of 11.4 months compared with 5.5 months in the placebo group ($p < 0.001$).¹⁵⁷ The second agent everolimus, an oral inhibitor of the mammalian target of rapamycin (mTOR) was also tested in a large (410 patients) international, randomized, double blind, placebo-controlled phase 3 trial (RADIANT-3), in patients with advanced low- and intermediate-grade PEN. The median progression free survival of patients in the everolimus arm was 11 months compared to 4.6 months in the placebo arm ($p < 0.001$). Both of these oral agents have a favorable side-effect profile, and further studies to delineate their role in the treatment of PENs are currently underway.¹⁵⁸

SECTION H: HEPATOBILIARY AND PORTAL VENOUS SYSTEM

Chapter 57

Hepatobiliary Anatomy

Trevor L. Nydam and Richard D. Schulick

Key Points

- 1 The most widely accepted nomenclature for liver anatomy is based on Couinaud's description of eight anatomic segments of the liver.
 - 2 There are three major hepatic veins, with most patients having a right hepatic vein that joins the right anterior wall of the inferior vena cava (IVC) and middle and left hepatic veins that converge into a common trunk before joining the IVC.
 - 3 Classic hepatic arterial anatomy exists in only approximately 50% of patients, with a replaced or accessory right hepatic artery arising from the superior mesenteric artery and a replaced or accessory left hepatic artery arising from the left gastric artery being the most common variants.
 - 4 Callot triangle is bounded by the common hepatic duct on the left, the cystic duct inferiorly, and the cystic artery superiorly.
 - 5 The blood supply of the common bile duct is segmental in nature and consists of branches from the cystic, hepatic, and gastroduodenal arteries, which meet to form collateral vessels that run in the 3 and 9 o'clock positions.
 - 6 Multiphase computed tomography (CT) and magnetic resonance imaging (MRI) with intravenous contrast are commonly used to characterize hepatic lesions.
 - 7 Magnetic resonance cholangiopancreatography (MRCP) is often used to view biliary anatomy as it involves no contrast agent and optimally can provide images that rival formal cholangiography.
 - 8 Intraoperative ultrasonography is used routinely to assess the anatomy of the hepatic pedicles (portal vein, hepatic artery, and bile duct) and hepatic veins and to identify and characterize hepatic lesions within the parenchyma and their relationships within the eight anatomic segments.
 - 9 The portal pedicles are invested with the Glisson capsule and have a very echogenic covering to them on ultrasound in contrast to hepatic vein branches.
 - 10 The steps involved in major hepatectomy include optimal exposure, vascular inflow control, vascular outflow control, and parenchymal transection.
-

A precise knowledge of the anatomy of the liver and biliary tract and their relationship to associated blood vessels is essential for the performance of hepatobiliary surgery. Every surgeon caring for a patient with a hepatobiliary problem should have a thorough understanding of the general anatomy and an absolute understanding of each individual patient's anatomy, because variations are common.

TOPOGRAPHIC ANATOMY

The normal adult liver is a large, wedge-shaped organ that occupies much of the right upper quadrant of the abdomen. Most of the liver bulk lays to the right of the midline where it molds to the undersurface of the right diaphragm, and where the lower border coincides with the right costal margin. The liver extends as a wedge to the left of the midline between the anterior surface of the stomach and the left dome of the diaphragm. The anterior surface of the liver is invested by visceral peritoneum that extends to the anterior abdominal wall in the midline from the ligamentum teres, or round ligament (the obliterated umbilical vessels), and by an obliquely oriented fusion of peritoneum known as the falciform ligament. Posteriorly, the investing peritoneum is contiguous with the peritoneum of the diaphragm and covers the liver, except for a *bare area* bounded by the *right and left triangular ligaments* (Fig. 57-1). The Glisson capsule is a thin, fibrous covering that envelops the liver deep to the peritoneum, sending fibrous septa into the hepatic parenchyma investing the portal structures.

Ordinarily, the liver can be separated from adjacent organs and structures by simply moving it or

dividing loose areolar tissue (Fig. 57-2). Neoplastic or inflammatory conditions may obliterate these planes. Superiorly and anteriorly, the diaphragm or abdominal wall and liver may jointly be involved in a pathologic process. Posteriorly, the right adrenal gland or upper pole of the right kidney may involve or be involved by the liver. Inferiorly, the gallbladder, colon, duodenum, or periportal lymphatics may be involved. Cancers of the stomach or gastroesophageal junction may involve the left liver or vice versa.

MORPHOLOGIC AND FUNCTIONAL ANATOMY

The description and definition of the anatomic divisions of the liver have been revised and written about numerous times in the past 100 years.¹⁻⁸ At present, there is still confusion between the various hepatic anatomic nomenclatures in the English and French literature. Based only on morphologic criteria and surface anatomy, the liver can be divided into right and left halves by forming a plane through the gallbladder fossa (Cantlie line) and inferior vena cava (IVC) (Fig. 57-3). As will be shown later, this plane approximates the true division between the right and left halves using the more strict definition of a plane through the middle hepatic vein and IVC, but the middle hepatic vein is not obvious based solely on morphology and without ultrasound. Further subdivisions of the right half of the liver into a right anterior sector and a right posterior sector are not possible based only on surface anatomy. The left half of the liver can be further subdivided into a left medial section and left lateral section based on the umbilical fissure and falciform ligament. The caudate (tail-shaped) process of the liver is identified as lying posterior to the gastrohepatic ligament and emanating from a process of liver situated posterior to the main portal pedicle and anterior to the IVC.

Figure 57-1. Posterior view of the liver, showing the level of peritoneal reflections.

Figure 57-2. Posterior view of the liver, showing organs that produce impressions on its inferior surface.

Figure 57-3. Anatomic division of the liver into right and left halves by a plane extending from the gallbladder fossa posteriorly to the inferior vena cava.

Figure 57-4. Functional divisions of the liver and liver segments according to Couinaud nomenclature with the liver in the natural position (A) and after it is mobilized (B).

1 The most widely accepted nomenclature is based on Couinaud's description of the discrete anatomic segments of the liver (Fig. 57-4).⁶ The eight segments of a liver can be determined using surface anatomy and location of the three main hepatic veins, the portal pedicle bifurcation into right and left, and the umbilical fissure and falciform ligament. As described, the right and left halves of the liver are delineated by a plane through the middle hepatic vein and IVC. Segments II, III, and IV lie to the left of this plane and form the left half of the liver. Segments V, VI, VII, and VIII lie to the right of this plane and form the right half of the liver. Segment I, or the caudate process, is morphologically distinct from the two halves of the liver and emanates from a process of liver lying posterior to the portal pedicle and anterior to the IVC. Whereas the right and left halves of the liver derive blood supply from the corresponding right and left portal veins and hepatic arteries, segment I derives blood supply from both. Additionally, the right half of the liver has venous drainage primarily through the right and middle hepatic veins, and the left half of the liver primarily through the left and middle hepatic veins. Segment I, however, drains directly via small branches into the IVC. The left liver and especially the right liver usually have small accessory hepatic venous branches draining directly into the IVC. Occasionally on the right, the accessory branch is significant in size.

The right half of the liver can be further subdivided using a plane through the right hepatic vein and the IVC. Liver anterior to this plane forms the right anterior sector, and liver posterior to this plane forms the right posterior sector. The right anterior sector of the liver is composed of segment V (inferior to the portal bifurcation) and segment VIII (superior to the portal bifurcation). The right posterior sector of the liver is composed of segment VI (inferior to the portal bifurcation) and segment VII (superior to the portal bifurcation).

The left half of the liver can be further subdivided using a plane through the umbilical fissure and falciform ligament. Liver medial to this plane forms the left medial section of the liver or segment IV, and liver lateral to this plane forms the left lateral section of the liver. The left medial section of the liver is sometimes divided into two halves, with IVa closer to the IVC and IVb farther. The left lateral section of the liver is further subdivided into segment II (which is superior) and segment III (which is inferior).

Hepatic Veins

2 Three major hepatic veins carry blood from the liver to the IVC. Most patients have a right hepatic

vein that joins the right anterior wall of the IVC and middle and left hepatic veins that converge into a common trunk about 1 cm from the IVC that enters the left anterior wall of the IVC (Fig. 57-5). In some patients, the three main hepatic veins join the IVC via three distinct trunks. These hepatic veins usually lie within the hepatic parenchyma. Usually, a definable extraparenchymal segment of the hepatic veins, especially the right, can be dissected out before it empties into the IVC, which makes outflow control safer and easier. Usually, multiple accessory right hepatic veins empty from the right half of the liver directly into the IVC as it courses posterior to the liver (Fig. 57-6). On occasion, these accessory right hepatic veins are sizable and may even support venous outflow should the native right hepatic vein need to be taken. Additionally, sometimes an umbilical vein can be appreciated running to the falciform ligament between the middle and left hepatic veins and emptying into the terminal portion of the left hepatic vein.

Portal Veins

The superior mesenteric and splenic veins join posterior to the neck of the pancreas to form the main portal vein. It receives pyloric and coronary vein branches as it courses cephalad and obliquely to the right to form the most posterior structure within the hepatoduodenal ligament (portal triad). In the hilus of the liver, the main portal vein bifurcates into a short oblique right portal vein and a longer, more transverse, and more superficial left portal vein (Fig. 57-7). These branches then enter the parenchyma and become invested along with the other components of the portal triad by extensions of the Glisson capsule. Both the right and left portal veins give off small branches to dually supply segment I. The right portal vein usually enters the hepatic parenchyma immediately and is quick to divide into a right anterior portal vein supplying segments V and VIII and a right posterior portal vein supplying segments VI and VII. The left portal vein may remain near the surface of the left half of the liver in the hilar plate for a significant distance as it courses to the umbilical fissure to give off medial branches to segment IV and lateral branches to segments II and III.

Figure 57-5. Three major hepatic veins drain the liver. The caudate segment of the liver usually drains directly into the inferior vena cava.

Figure 57-6. Retraction of right liver medially exposes small venous tributaries that drain the right liver directly into the retrohepatic vena cava. Several branches are ligated.

Figure 57-7. Intrahepatic divisions of the portal vein.

Figure 57-8. Variations in hepatic arterial anatomy.

Hepatic Arteries

3 There is much variability in the hepatic arterial supply to the liver. The most common anatomy is a common hepatic artery that arises from the celiac trunk and courses near the superior border of the neck of the pancreas. After the origins of the gastroduodenal, supraduodenal, and right gastric arteries, the proper hepatic artery courses in the left anterior aspect of the hepatoduodenal ligament in front of the portal vein and to the left of the common hepatic duct. The proper hepatic artery usually bifurcates into right and left hepatic arteries outside the liver. The anatomy of the hepatic artery is variable and should be familiar to surgeons operating in this area (Fig. 57-8). Approximately 45% of people have variant hepatic arterial anatomy.⁹ The right hepatic artery usually courses posterior to the common hepatic duct but anterior to the right portal vein to supply the right liver. The left hepatic artery usually remains extrahepatic until near the base of the umbilical fissure, where it enters the liver to give off branches to segments II, III, and IV. Small branches from near the bifurcation of the proper hepatic artery also supply segment I. A middle hepatic artery branch may arise from either the right or left hepatic arteries after bifurcation. Although this anatomy is described as normal, it is found only in approximately 50% to 60% of patients. A replaced or accessory right hepatic artery may arise off of the superior mesenteric artery near its origin and course posteriorly or through the head of the pancreas to lie along the right posterior border of the hepatoduodenal ligament. A replaced or accessory left hepatic artery may arise off of the left gastric artery and course transversely toward the base of the umbilical fissure in the lesser omentum. In general, within the hepatic parenchyma, the hepatic arterial branches course closely with bile duct branches and fairly closely with portal venous branches, but not always, and anatomic variations should be suspected. The descriptions and frequency of hepatic arterial variants have been well characterized by Michels.⁹

Intrahepatic Biliary Tree

The right and left livers are respectively drained by the right and left hepatic ducts, whereas the caudate (segment I) is drained by several small ducts joining the confluence and the first several centimeters of

both hepatic ducts. The intrahepatic ducts are tributaries of the corresponding hepatic ducts, which penetrate the liver invaginating the Glisson capsule at the hilus. Bile ducts are usually located above the corresponding portal branches, whereas hepatic arterial branches run inferiorly to the veins. The left hepatic duct directly drains the bile ducts to segments II, III, and IV, which constitute the left liver. The right hepatic duct drains the bile ducts from segments V, VI, VII, and VIII, which constitute the right liver. Usually, the bile ducts from segments V and VIII join to first form the anterior sectoral duct and the bile ducts from segments VI and VII join to first form the posterior sectoral duct prior to forming the right hepatic duct (Fig. 57-9).

Figure 57-9. Intrahepatic divisions of the bile ducts and hepatic arteries.

Gallbladder

4 The gallbladder is a reservoir for bile located on the undersurface of the liver at the confluence of the right and left halves of the liver. It is separated from the hepatic parenchyma by a cystic plate, which is constituted of connective tissue applied to the Glisson capsule. The gallbladder may be deeply imbedded into the liver or occasionally presents on a mesenteric attachment, but usually lays in a gallbladder fossa. The gallbladder varies in size and consists of a fundus, a body, and an infundibulum. The tip of the fundus usually reaches the free edge of the liver and is closely applied to the cystic plate. The infundibulum of the gallbladder makes an angle with the body and may obscure the common hepatic duct, constituting a danger point during cholecystectomy. The cystic duct arises from the infundibulum of the gallbladder and extends to join the common hepatic duct. The lumen measures between 1 and 3 mm in diameter, and its length varies depending on the type of union with the common hepatic duct (Fig. 57-10). Callot triangle is bounded by the common hepatic duct on the left, the cystic duct inferiorly, and the cystic artery superiorly. Arterial blood reaches the gallbladder via the cystic artery, which usually originates from the right hepatic artery. Several known variations in the origin and course of the cystic artery are illustrated in Figure 57-11. The venous drainage of the gallbladder is directly into the liver parenchyma or into the common bile duct plexus.

Figure 57-10. Variations in the junction of the cystic duct and common hepatic duct.

Figure 57-11. Variations of the cystic artery.

Common Bile Duct

The cystic and common hepatic ducts join to form the common bile duct. The common bile duct is approximately 8 to 10 cm in length and 0.4 to 0.8 cm in diameter. The common bile duct can be divided into three anatomic segments: supraduodenal, retroduodenal, and intrapancreatic (Fig. 57-12). The supraduodenal segment resides in the hepatoduodenal ligament lateral to the hepatic artery and anterior

to the portal vein (Fig. 57-13). The course of the retroduodenal segment is posterior to the first portion of the duodenum, anterior to the IVC, and lateral to the portal vein. The pancreatic portion of the duct lies within a tunnel or groove on the posterior aspect of the pancreas. The common bile duct then enters the medial wall of the duodenum, courses tangentially through the submucosal layer for 1 to 2 cm, and terminates in the major papilla in the second portion of the duodenum (Fig. 57-12). The distal portion of the duct is encircled by smooth muscle that forms the sphincter of Oddi. The common bile duct usually joins the pancreatic duct to form a common channel before entering the duodenum at the ampulla of Vater. Some patients will have an accessory pancreatic duct emptying into the duodenum.

5 The blood supply of the common bile duct is segmental in nature and consists of branches from the cystic, hepatic, and gastroduodenal arteries. These meet to form collateral vessels that run in the 3 and 9 o'clock positions. The venous drainage forms a plexus on the anterior surface of the common bile duct that enters the portal system. The lymphatic drainage follows the course of the hepatic artery to the celiac nodes.

LIVER IMAGING

Computed Tomography

Computed tomography (CT) is widely available and quick and has become the main modality to initiate the assessment of hepatic processes. It also has the advantage of being able to quickly assess other organs within the abdominal cavity and chest. With the introduction of multidetector spiral CT, the resolution of hepatic lesions is quite good. This scanning technique allows total hepatic imaging in arterial, portal venous, and delayed phases after a rapid intravenous contrast bolus during a single breath hold by the patient (Fig. 57-14). In addition, three-dimensional reconstructions can be created to construct high-quality hepatic artery angiograms, portal venograms, and hepatic venograms. These reconstructions play a vital role in the selection of appropriate donors for live donor liver transplantation (Fig. 57-15). Drip infusion cholangiography with CT can provide distal intrahepatic duct cholangiograms that with the three-dimensional arteriograms and venograms are vital in planning donor hepatectomies and avoiding serious complications.

Figure 57-12. Anatomy of the extrahepatic biliary tree and pancreatic duct.

Figure 57-13. Relationship of structures within the hepatoduodenal ligament.

Figure 57-14. Portal venous phase of computed tomography (CT) scan from a patient with a history of colorectal cancer and three lesions in the liver. Lesion 1 in segment VIII is irregular and rim enhancing and was a colorectal cancer metastasis. Lesion 2 straddling segments IV and VIII has smooth borders, is not rim enhancing, and was found to be a cyst. Lesion 3 straddling segments IV and III across the umbilical fissure is irregular and rim enhancing and was a colorectal cancer metastasis.

Magnetic Resonance Imaging

6 Magnetic resonance imaging (MRI) of the liver with gadolinium as a contrast agent is commonly used

to help further characterize hepatic lesions. Resolution of some lesions may be slightly better with MRI. Additionally, certain lesions, such as hemangiomas and cysts, can easily be identified based on MRI characteristics when the CT characteristics are indeterminate (Fig. 57-16). The disadvantages of MRI are its increased cost, increased amount of time to perform, inability to quickly screen other organs and body cavities within the same session, and wide variability in quality from one imaging center to another.

7 Magnetic resonance cholangiopancreatography (MRCP) is becoming more widely used to noninvasively view biliary anatomy (Fig. 57-17). The scans are heavily T2 weighted, which maximizes the signal from the biliary tree. No injection of contrast agent is needed, and under optimal conditions the resulting imaging can rival that of formal cholangiography. Three-dimensional reconstructions can be performed to view the biliary tree from multiple angles and can be helpful in distinguishing between stones, strictures, and neoplasms. Again, these reconstructions are vital to donor selection in live donor liver transplantation. Rarely is it necessary to proceed with endoscopic retrograde cholangiopancreatography (ERCP) to define the distal intrahepatic ductal anatomy.

Figure 57-15. Three-dimensional reconstruction of the hepatic vasculature.

Ultrasonography

8 Hepatic ultrasonography can be applied transcutaneously or intraoperatively via open or laparoscopic surgery. It can be useful in identifying lesions within the hepatic parenchyma, to describe the consistency (i.e., fatty or cirrhotic) and identify dilation of the biliary tree and any abnormalities or stones within the gallbladder. In hepatobiliary surgical centers, intra operative ultrasonography is used routinely to assess the anatomy of the pedicles (portal vein, hepatic artery, and bile duct), the hepatic veins, and the hepatic parenchyma. It is useful both to further identify and characterize lesions within the hepatic parenchyma and to delineate their relationships within the eight anatomic segments of the liver. Additionally, it is often helpful to delineate proximity of lesions to major vascular structures and to survey for abnormal anatomy in planning a resection.

With ablation therapies more commonly employed, ultrasound has become indispensable in directing the use of radiofrequency ablation. This ablation therapy can be performed percutaneously, laparoscopically, and during open surgery.

9 Typically, intraoperative assessment of the liver involves examining the portal pedicles. The main portal pedicle is identified within the hepatoduodenal ligament. It is followed superiorly to the portal bifurcation into the main right and left pedicles. The portal pedicles are invested with the Glisson capsule and have a very echogenic covering to them in contrast to hepatic vein branches. The main right portal pedicle is followed toward the right where it gives off an anterior branch and a posterior branch (Fig. 57-18A). The right anterior branch gives off separate pedicles to segment V (caudad) and to segment VIII (cephalad). The right posterior branch gives off separate pedicles to segment VI (caudad) and to segment VII (cephalad). The main left pedicle is usually much longer and courses intact to the base of the umbilical fissure before branching into various segmental pedicles (Fig. 57-18B). At the base of the umbilical fissure, the main left pedicle courses anteriorly toward the round ligament and gives off a pedicle to segment IV medially and pedicles to segments II and III laterally. Next, if the falciform ligament has been divided, the hepatic veins can easily be visualized using intraoperative ultrasonography (Fig. 57-18C). As described previously, usually a larger right hepatic vein can be

delineated and smaller left and middle hepatic veins joining into a common trunk before emptying into the IVC are seen. Commonly, an umbilical hepatic vein branch can be identified coursing between the middle and left hepatic veins and running under the falciform ligament. Not uncommonly, significant accessory right hepatic veins can be seen emptying from the posterior surface of the right liver directly into the IVC as it courses posterior to the liver. The identification of these accessory right hepatic veins is potentially important for both vascular control and preservation of outflow from the liver (in occasional cases where outflow of the remnant right liver can be supported by a very large accessory vein). Finally, the hepatic parenchyma is systematically scanned to identify lesions within the liver (Fig. 57-18). It is sometimes useful to adjust the ultrasound settings on a known lesion defined preoperatively to maximize the echogenicity in the hopes of identifying other occult lesions not identified preoperatively.

Figure 57-16. A,B: T1-weighted magnetic resonance imaging (MRI) with gadolinium from the same patient as in Figure 57-14 with history of colorectal cancer and three lesions in the liver. Lesion 1 in segment VIII is irregular and rim enhancing and was a colorectal cancer metastasis. Lesion 2 straddling segments IV and VIII has smooth borders, is not rim enhancing, and was found to be a cyst. Lesion 3 straddling segments IV and III across the umbilical fissure is irregular, rim enhancing, and was a colorectal cancer metastasis. C,D: T2-weighted MRI from the same patient with history of colorectal cancer and three lesions in liver. Lesion 1 in segment VIII is irregular and mildly bright and was a colorectal cancer metastasis. Lesion 2 straddling segments IV and VIII has smooth borders, is very bright, and was found to be a cyst. Lesion 3 straddling segments IV and III across the umbilical fissure is mildly bright and was a colorectal cancer metastasis. Colorectal metastases and many tumors are mildly bright on T2-weighted MRI, whereas cysts and hemangiomas are typically very bright.

Positron Emission Tomography

Positron emission tomography (PET), especially when combined with CT (PET-CT), has become a valuable tool in helping to select patients who will most benefit from aggressive liver resection. This technique is based on the increased metabolism of glucose in neoplastic tissues. A glucose analog, fluorodeoxyglucose, that is tagged with fluorine-18 is injected intravenously before scanning and is retained preferentially in metabolically active tumors over normal tissue. Sometimes PET scans will identify areas of occult disease within the liver, but more importantly, they can identify areas of extrahepatic occult disease previously unsuspected. When combined with a CT scanner within the same machine and the ability to fuse images, the areas of increased activity can be more precisely anatomically identified (Fig. 57-19).

Figure 57-17. Magnetic resonance cholangiopancreatography (MRCP) of a patient after cholecystectomy with mild dilation of common hepatic duct (CHD). The pancreatic duct (PD) is also visible.

Correlation of Computed Tomographic Images with Segmental Anatomy

Preoperative CT remains the primary imaging modality used by most surgeons before hepatic resection. [Figure 57-14](#) is provided to help correlate CT images to the segmental anatomy defined previously. The segments of the liver are defined using identifiable structures on the CT ([Fig. 57-20](#)).

PREOPERATIVE EVALUATION OF HEPATIC RESERVE

Whenever a surgical resection is planned, an important consideration is whether the remnant liver will be sufficient to regenerate and sustain the patient long term. In patients with relatively normal hepatic parenchyma (without active hepatitis, cirrhosis, or metabolic defects), up to 75% of the hepatic volume can be resected with good recovery as long as the remnant liver has adequate portal venous and hepatic arterial inflow, adequate hepatic venous outflow, and adequate biliary drainage. Many groups around the world have used various strategies to predict hepatic reserve ([Tables 57-1](#) to [57-3](#)). None of these tests or strategies has been demonstrated to clearly better predict outcome than another. Many centers in the United States rely simply on the Child–Pugh or MELD score and the prediction of adequate liver remnant volume after resection. In select circumstances, it may be of benefit to perform portal vein embolization to the right or left half (rare) of the liver in the hopes of obtaining compensatory hypertrophy of the other side before resection. This is especially useful when the predicted liver remnant after resection is small or if the patient has an underlying hepatic dysfunction that may not allow the remnant to fully regenerate and sustain the patient long term. To gain maximal growth of the left lateral section of the liver, some centers will also embolize the portal vein branches to segment IV in addition to the main right portal vein. The disadvantages of portal vein embolization include the need to wait 3 to 4 weeks before resection to allow the compensatory hypertrophy to occur and, for more central lesions, the need to commit to taking out one or the other side with an extended hepatectomy without the benefit of intraoperative evaluation.

Figure 57-18. A,B: Intraoperative ultrasound images of liver demonstrating right hepatic pedicle (RHP), right anterior sector pedicle (RASP), right posterior sector pedicle (RPSP), left hepatic pedicle (LHP), segment II pedicle (SIIP), segment IV pedicle (SIVP), segment I (SI), and inferior vena cava (IVC). C,D: Intraoperative ultrasound images of liver demonstrating inferior vena cava (IVC), right hepatic vein (RHV), middle hepatic vein (MHV), left hepatic vein (LHV), segment I (SI), and a metastatic gastrointestinal stromal tumor lesion straddling segments IV and V of the liver.

Figure 57-19. Positron emission tomography and computed tomography (PET-CT) scan images of patient in Figure 57-18B and C with solitary gastrointestinal stromal tumor metastasis straddling segments IV and V. Noncontrast CT images (**left**). PET images (**center**). Fusion images (**right**).

Table 57-1 Strategies to Predict Hepatic Reserve

- Child-Pugh score (Table 57-2) to assess synthetic ability (albumin, prothrombin time, and ascites), bile conjugation and excretory function (total bilirubin), and metabolic function (changes in mental status from ammonia retention)
- Model for End-Stage Liver Disease (MELD) score estimates 3-mo mortality in patients with chronic liver disease (Table 57-3)
- Clearance of galactose or organic anionic dyes, such as indocyanine green
- Tests of microsomal function such as caffeine clearance, lidocaine clearance, or aminopyrine breath tests
- Volumetric measurements of the liver and prediction of liver remnant after resection based on three-dimensional reconstructions from computed tomography and magnetic resonance imaging

ONCOLOGIC CONSIDERATIONS IN HEPATIC RESECTION

The decision of when and whether to operate is often just as important as the technical details of successfully removing a liver lesion(s) identified in a patient. It is very important to consider the likely diagnosis in making the decision of whether to operate. For example, a solitary liver lesion presenting in an elderly patient with a rising carcinoembryonic antigen (CEA) and a recent history of a resected colon cancer should be treated differently from a young woman with a solitary lesion with radiologic characteristics of a focal nodular hyperplasia lesion. It is important to consider the biology of the tumor within the patient. For example, a patient who represents with a solitary hepatic colorectal cancer metastasis 4 years after resection of the primary tumor will more likely benefit from hepatic resection than another patient who presents with eight synchronous lesions in the liver at the time of diagnosis of the primary tumor. It is important to consider whether the goal of resection is curative or palliative. For example, patients with neuroendocrine tumor metastases of the liver may be debulked of hepatic metastases, but they are rarely totally eradicated of disease. If the tumor is functional and difficult to control medically, then there may be a benefit to debulking. Even if the tumor is not functional, some

evidence indicates that surgical debulking of liver metastases in carefully selected patients may benefit long-term survival. It is important to exclude other distant extrahepatic disease with a reasonable number of preoperative tests. For example, before performing hepatic resection for colorectal cancer metastases, it is often helpful to obtain a PET scan to exclude extrahepatic metastases. This will allow better selection of patients most likely to benefit from hepatic resection and will allow patients with previously unsuspected systemic disease to get systemic therapy sooner.

Table 57-2 Child–Pugh Classification

	1 Point	2 Points	3 Points
Bilirubin (mg/dL)	<2	2–3	>3
Albumin (g/dL)	>3.5	2.8–3.5	<2.8
Ascites	Absent	Moderate	Severe
Encephalopathy	Absent	Moderate	Severe
Prothrombin time Seconds prolonged	<4	4–6	>6
INR	<1.7	1.7–2.3	>2.3

INR, international normalized ratio.
Child-Pugh Class A: 5-6 points; Class B: 7-9 points; Class C: 10-15 points.

Table 57-3 MELD Score

MELD = 3.78 × ln[serum bilirubin (mg/dL)] + 11.2 × ln[INR] + 9.57 × ln[serum creatinine (mg/dL)]
40 or more—71.3% 3-month mortality
30–39—52.6% 3-month mortality
20–29—19.6% 3-month mortality
10–19—6.0% 3-month mortality
<9—1.9% 3-month mortality

Patient on renal replacement therapy (dialysis twice within the last week or >24 hours of CVVHD within the last week) will have a serum creatinine level of 4.0 mg/dL.

The comorbid status of the patient is also important. Extended hepatic resections with or without biliary reconstruction can exert a toll on even very fit patients. It is important to identify patients who may have difficulties with hepatic regeneration (e.g., those with a history of hepatitis, cirrhosis, or metabolic disorders). Patients with suspected cardiopulmonary disease should undergo appropriate preoperative evaluation and treatment before hepatic resection. Finally, other effective treatments and the optimal sequence of treatments should be considered. For example, in the treatment of hepatocellular carcinoma the possibilities include liver transplantation, liver resection, radiofrequency or microwave ablation, transarterial chemoembolization, and systemic chemotherapies. A patient with limited hepatocellular carcinoma and poor hepatic reserve due to chronic liver disease, cirrhosis, and portal hypertension is best treated with liver transplant, whereas a patient with normal liver parenchyma, minimal portal hypertension, and a resectable lesion may be best treated with liver resection. Additionally, some patients may best be treated with ablative techniques, especially if they have very small lesions that are easily approached percutaneously. Many patients are treated with a combination of these modalities. For example, most transplant centers will first treat hepatocellular carcinoma patients with chemoembolization to provide locoregional control while the patient is upgraded on the waiting list. Whether the patient is a candidate for liver transplantation or resection, this combination can give insight into the biology of the disease prior to definitive treatment.

INTRAOPERATIVE ASSESSMENT

Incisions for open hepatic resections usually involve a right subcostal incision. Significant exposure can be obtained with a trifurcated incision as shown in [Figure 57-21](#). In the majority of cases, however, all that is needed is an extended right subcostal incision with a vertical extension to the base of the xiphoid. The xiphoid can be resected for better exposure. For bulky lesions on the left or if the left half of the liver extends significantly to the left upper quadrant, a left subcostal component can be added. In rare circumstances, especially for lesions high on the dome, an intercostal extension or even median sternotomy may improve exposure. This is especially true for lesions involving the hepatic vein and IVC confluences.

Several versions of self-retaining costal margin retractors or ringed retractors are available that provide good access to the subdiaphragmatic surface. For complete intraoperative ultrasonography and for major resections, complete mobilization of the involved side of the liver is required. The round ligament is divided and the falciform ligament divided. The right and/or left triangular ligaments are then divided to expose the bare areas of the liver. During exposure of the bare areas of the liver, care should be taken to avoid entering the right or left chest through the ligamentous portions of the diaphragm because this will cause excessive bellowing of the diaphragm and poor exposure until a chest tube is placed on that side or the hemithorax is “bubbled out” to remove the air and the diaphragm repaired. Additionally, the right and left phrenic veins are very superficial on the hemidiaphragm and can be injured. The right colon can be mobilized out of the field by dividing Gerota fascia over the right kidney and pulling the hepatic flexure inferiorly. To completely assess the caudate lobe, the overlying lesser omentum should be divided. Care should be taken to avoid inadvertently dividing a replaced or accessory left hepatic artery running in this space. After mobilization, a thorough bimanual examination should be performed and intraoperative ultrasonography used as previously described.

Figure 57-21. Incisions used for open hepatic resection.

Figure 57-22. Lowering the hilar plate. **A:** The inferior border of segment IV overlies the hepatic duct confluence. **B:** Division of the connective tissue investment allows elevation of segment IV, which results in a “lower” hilar plate and surgical exposure to the hepatic duct confluence.

10 The porta hepatis is often dissected to identify the main bifurcations of the hepatic artery and portal vein and the confluence of the bile ducts. This allows individual ligation of the branches of these structures supplying one side of the liver while preserving the branches to the other side. Ligation of the hepatic artery and portal vein to one side also allows the liver parenchyma to demarcate a line of

resection between the right and left liver. Greater exposure of the superior aspect of the hepatic hilum and exposure of a high or intraparenchymal bifurcation of a portal triad structure may be aided by exposing the hilar plate (Fig. 57-22) and dividing the Glisson capsule at the most inferior border of segment IV. Inflow control to the liver can also be obtained by pedicle ligations in which small hepatotomies are made around the main right pedicle, main left pedicle, right anterior pedicle, or right posterior pedicle after identification with ultrasound (Fig. 57-23).¹⁰ The pedicle of interest can be dissected out bluntly with a right angle or by palpation. The pedicle can then be clamped to confirm that it does indeed supply the area of liver of interest (i.e., right half, left half, right anterior section, or right posterior section). Once confirmed, the pedicle can be divided. Alternatively, the inflow pedicles can be divided as they are encountered while transecting hepatic parenchyma. With this technique, hemorrhage can be minimized by intermittent portal inflow occlusion, which is accomplished by gently clamping the main portal triad within the hepatoduodenal ligament (“Pringle maneuver”).

Outflow control of the hepatic veins can be obtained before or after hepatic transection and should be decided on a case-by-case basis. When there is a significant extraparenchymal component to the hepatic vein(s), often it is easier to divide the hepatic vein(s) early and before parenchymal transection (but after inflow control) (Fig. 57-24). When the extraparenchymal component to the hepatic vein(s) is very short or absent and when the tumor margin is not near the junction of the hepatic vein(s) and IVC, it may be easier and safer to divide the hepatic vein(s) within the hepatic parenchyma after most of the parenchymal transection has been performed. The use of endoscopic vascular stapling devices has made the ligation of hepatic veins, whether extra- or intraparenchymally, much quicker and safer (Fig. 57-25).¹⁰ It is often useful to keep the central venous pressure (CVP) of the patient low (<5 mm Hg) until after parenchymal transection as this will decrease bleeding from the IVC and hepatic vein branches.¹¹

Figure 57-23. Hepatotomies to access pedicles for ligation: right hepatectomy, 1 and 2; left hepatectomy, 3 and 5; right anterior sectorectomy, 2 and 4; and right posterior sectorectomy, 1 and 4.

During live donor hepatectomy, a meticulous dissection of the portal triad is done isolating the main bifurcations of the hepatic artery, bile duct, and portal vein on the side that will be recovered. A cholecystectomy and trans-cystic intraoperative cholangiogram is performed to confirm the biliary anatomy. Outflow control is obtained by dissection of the extrahepatic portion of the hepatic veins as previously described. After the graft hemiliver has been dissected off the IVC, the parenchyma is transected while ensuring continued inflow and outflow to both sides limiting any ischemia to the graft and remnant liver. The portal triad structures and the hepatic vein are divided and the graft is removed in coordination with the recipient operation.

Over the last decade there has been significant advances in minimally invasive liver resection. In large volume hepatobiliary centers with advanced laparoscopic skills both benign and malignant tumors in the peripheral segments (II to VI) are safely resected with good results. With more experience, formal hemihepatectomies are becoming more common. As with other laparoscopic operations, advantages include decreased postoperative pain, decreased length of stay, and earlier return to normal activity. A minimally invasive liver resection should proceed with the same indications and intraoperative steps employed in an open resection. The indications to resect benign tumors should not be broadened because an operation with potentially less associated morbidity can be offered to the patient. As with open resections, major minimally invasive liver resections include optimal exposure, vascular inflow and outflow control prior to parenchymal transection. Options for minimally invasive liver resection include a purely laparoscopic approach that does not employ the planned use of a hand port or mini-laparotomy incision. The specimen is removed through an extension of one of the laparoscopic port incisions or a small Pfannenstiel incision. The planned use of a hand port is an option for resections that require more manual control. Hybrid procedures that utilize the laparoscope to mobilize the liver and then proceed with a mini-laparotomy for the portal triad dissection and

parenchymal are use by many for major resections. As centers gain more experience the trend is to perform more resections with the purely laparoscopic approach. Minimally invasive liver resection will progressively be used for more complex cases including live donor hepatectomies.

Figure 57-24. Caudal retraction of the left hepatic lobe with division of middle and left hepatic veins during left hepatic lobectomy. Often, the division of the middle and left hepatic veins is intraparenchymal.

Figure 57-25. A vascular endoscopic stapling device is used to divide the right hepatic vein after the right side of the liver has been mobilized.

MAJOR HEPATECTOMIES

To develop a uniform nomenclature understood by all, the American and International Hepato-Pancreato-Biliary Associations (AHPBA and IHPBA) have adopted the Brisbane 2000 terminology of hepatic anatomy and resections. Right hepatectomy or right hemihepatectomy involves the resection of segments V through VIII. Left hepatectomy or hemihepatectomy involves the resection of segments II through IV. Either of these resections may or may not include resection of segment I, which should be stated. Extended right hepatectomy involves the resection of segments IV through VIII. Extended left hepatectomy involves the resection of segments II through V plus VIII. Again, either of these extended resections may or may not include resection of segment I, which should be stipulated.

Right anterior sectorectomy includes segments V and VIII. Right posterior sectorectomy includes segments VI and VII. Left medial sectionectomy removes segment IV. Left lateral sectionectomy includes segments II and III. A segmentectomy involves the resection of a single segment and a bisegmentectomy involves the resection of two contiguous segments.

The steps involved in each of these major hepatectomies include optimal exposure of the liver, vascular inflow control, vascular outflow control, and parenchymal transection. Vascular inflow control can be obtained by directly ligating the main right or left branches of the hepatic artery and portal vein in the hilum or by intermittent 10- to 20-minute intervals of a Pringle maneuver with 3 minutes in between to reestablish blood flow (or both). It is the authors' preference to encircle the hepatoduodenal

ligament twice with a quarter-inch Penrose drain that is tightened and clamped for a Pringle maneuver. Pedicle ligation can also be performed, as described previously, or the pedicles can be controlled as they are encountered during parenchymal transection. It is the authors' preference to obtain vascular inflow by ligating the appropriate vessels in the hilum or by pedicle ligations and to supplement this with intermittent Pringle maneuvers, as necessary, during parenchymal transection. Often the Pringle maneuver is not required, but if bleeding from inflow vessels becomes significant, then it should be performed. Vascular outflow to the right or left liver can be obtained by exposing and ligating the hepatic veins, as previously described, or by ligating the vessels intraparenchymally during transection of the liver tissue. Parenchymal transection can be performed using a multitude of techniques including finger fracture, using a Kelly clamp to fracture, Cavitron Ultrasonic Surgical Aspirator (CUSA), harmonic scalpel, stapling devices, electrocautery devices with or without saline perfusion, high-pressure water jets, and radiofrequency planar arrays. The superiority of any one of these techniques has not been established, and all are used. With these techniques, individual blood vessels and bile ducts are cauterized, clipped, or sutured in rapid succession as they are encountered. Constant reevaluation of the direction of transection is important both to not injure vital structures to the remnant liver and to maintain a negative margin. After parenchymal transection and removal of the specimen, the raw surface of the liver is carefully inspected for bleeding and bile leakage, which can then be controlled by suture ligation and the use of argon beam coagulation. The authors' preferences are to selectively use closed suction drains near resected liver surfaces to monitor and drain unrecognized postoperative bile leaks. Some centers have decreased the use of closed suction drains in favor of radiologic intervention when necessary, because they often clog or do not actually drain the fluid collections that form.

SEGMENTAL RESECTIONS

To maximize functional reserve, (multi)segmental or subsegmental (or nonanatomic) hepatectomies can be performed. For example, left lateral sectionectomy (segments II and III), central hepatectomy to remove the right anterior section (segments V and VIII) and left medial section (segment IV), right posterior sectionectomy (segments VI and VII), or caudate resection (segment I) are examples in which one, two, or three contiguous segments are removed to eradicate tumors within those regions of the liver. These resections are often done with intermittent Pringle maneuvers until the specific pedicles supplying these areas are controlled.

Chapter 58

Hepatic Infection and Acute Liver Failure

Andrew M. Cameron and Christine Durand

Key Points

- 1 Pyogenic abscess is increasing due to the rise of invasive procedures involving the liver, biliary tree, and pancreas.
 - 2 The treatment for hydatid cysts is surgical resection after the introduction of antiparasitic medication.
 - 3 Viral hepatitis due to hepatitis B and C represents a principal cause of chronic liver disease in the United States and worldwide, newer antiviral agents have made these diseases treatable or curable.
 - 4 Liver transplant is the treatment of choice for decompensated cirrhosis or early hepatocellular cancer in a cirrhotic liver.
 - 5 One-third of acute liver failure patients will die without a liver transplant. Results after liver transplant show greatly improved survival, though still inferior to that seen with transplantation for chronic disease.
-

PYOGENIC LIVER ABSCESS

Abscess in the liver due to bacteria is known as pyogenic abscess. Pyogenic liver abscess occurs relatively infrequently (incidence of 2.3 cases per 100,000 population) but still represents around 13% of abdominal abscesses. It most frequently occurs in the setting of bowel compromise in which spread to the liver is via the portal circulation or in the setting of direct spread from the biliary tree. Pyogenic abscess may also occur as a result of seeding in the setting of systemic infection.¹ Lastly, hepatic abscess is seen in liver transplant recipients and when observed suggests hepatic artery compromise (Fig. 58-1).

1 Over the past 20 years the increase in invasive procedures involving the liver, biliary tree, and pancreas has resulted in an increase in the rate of pyogenic abscess. Most pyogenic abscesses are solitary and polymicrobial and involve the right lobe of the liver. Individuals over 50 years of age, diabetics, liver transplant recipients, and those with malignancy are at the highest risk for pyogenic abscess.

Fever is the most frequent presenting symptom of pyogenic liver abscess, sometimes without other localizing signs. Right upper quadrant pain, chills, anorexia, weight loss, malaise, weakness, and jaundice are frequently present. Laboratory studies show elevated white blood cell count in most cases, though not always. Abnormal liver function tests, including elevated bilirubin or transaminases are seen in about half of the cases.^{2,3}

Though a chest x-ray may reveal a right pleural effusion or elevated hemidiaphragm in 50% of cases, the radiographic test of choice is ultrasound (US) or CT scan. US will reveal abscess in 90% of cases and can guide drainage. CT is even more sensitive and will reveal small abscesses and differentiate these lesions from other pathology.⁴

Causative agents in hepatic abscess are gram-negative aerobes in two-thirds of patients, most commonly *Escherichia coli*, *Klebsiella pneumoniae*, and *Proteus* species. Enterococci may also be present if the cause of the abscess is biliary; anaerobes may be isolated if the source is colonic. Streptococci species are frequently found as well. These microbes will be isolated from the lesion and the blood in most patients and it is helpful to draw blood cultures prior to the administration of antibiotics. Coverage should be broad and its duration is based on clinical response. A typical course is 14 days of IV antibiotics followed by oral medication for a total of 6 weeks.⁵⁻⁷

Percutaneous drainage is standard at this time and is almost always easily accomplished. A drainage catheter should be left in place until output is minimal, often around 7 days. If attempt at percutaneous drainage is complicated by ascites, multiple abscesses, transpleural approach, large size, or other consideration, an open approach may be required. Adequate drainage and prompt initiation of

antibiotics are crucial, without which mortality rates are high. Other contributors to poor outcome include: multiple abscesses, non-Klebs pathogens, mixed bacterial and fungal abscesses, presence of respiratory symptoms, presence of malignancy, and large size (> 5 cm).^{8,9}

AMEBIC LIVER ABSCESS

Amebic liver abscesses are caused by *Entamoeba histolytica*, a protozoan. Systemic infection, or amebiasis, is most commonly asymptomatic, clinical manifestations include amebic dysentery and extraintestinal manifestations. Amebic liver abscess is the most common extraintestinal manifestation and is due to ascending portal infection. Amebiasis is most prevalent in tropical and subtropical regions with poor sanitation, as fecal–oral transmission is the most common route of infection. It is estimated that 40 to 50 million are infected each year worldwide, and in the United States the highest rates are seen in immigrants from endemic areas. Again, most infections are asymptomatic, but amebic dysentery, and pulmonary, cardiac, and brain involvement can occur, along with hepatic abscess.

Hepatic abscess occurs in only around 5% of cases of amebiasis. Men are affected 10 times more commonly than women, peak incidence is in the third, fourth, or fifth decade of life, and corticosteroid usage is a risk factor.^{2,10} Ingested cysts pass through the stomach and reach the intestine. There the cyst wall is degraded and trophozoites are released. These infective particles multiply in the colonic lumen and then may enter mesenteric veins and eventually the liver. Amebic trophozoites there cause obstruction of venules, thrombosis and infarction of hepatic parenchyma, with resultant abscess formation (Fig. 58-2).

Figure 58-1. Computed tomogram of a pyogenic hepatic abscess in a liver transplant recipient with occlusion of the hepatic artery.

Amebic liver abscesses range in size from several millimeters to massive (Fig. 58-3). Clinical presentation is typically 8 to 20 weeks following return from endemic area and usually manifests as right upper quadrant pain and fever. Cough, sweating, malaise, weight loss, and hiccough may be present. Amebic abscesses are more common in the right lobe and tend to be singular. Lesions may show an enhancing rim and when drained contained a dark, hemorrhagic, proteinaceous fluid often referred to as “anchovy paste” (Fig. 58-4). Abscesses have been described in the past as acute or chronic, and as benign or aggressive. Bacterial superinfection of amebic abscesses can occur and amebic abscesses can rupture into surrounding tissues or spaces, most frequently into the chest.^{1,2,10-14} *E. histolytica* is not found in stool specimens of infected patients but diagnostic antibodies are present in the serum 7 to 10 days after the onset of symptoms in almost all patients.¹⁵ Chest x-ray is frequently abnormal but CT scan is the diagnostic test of choice, often displaying the enhancing wall and a surrounding edema. MRI will likewise be diagnostic.^{2,10,12}

Treatment is based on amebicidal drugs to eliminate liver organisms and a luminal agent to eliminate intraluminal cysts even if not seen in the stool given the low sensitivity of microscopy to identify organisms. Preferred tissue agents include metronidazole 500 to 750 mg three times a day for 7 to 10 days. Tinidazole 2 g orally for 5 days is an alternative treatment that is better tolerated. To eradicate intraluminal cysts, the following regimens can be used: paromomycin (25 to 30 mg/kg/day orally three times a day for 7 days), diiodohydroxyquin (650 mg orally three times a day for 20 days), or diloxanide

furoate (500 mg orally three times daily for 10 days for adults). Metronidazole treats both intestinal and extraintestinal sites. Amebic abscesses can almost always be treated with medical therapy alone. Percutaneous drainage is considered in cases with poor response, when superinfection is suspected, or if there is risk of rupture. Open surgical drainage is almost never required and would be considered only in severe complicated cases.^{2,10,13}

ECHINOCOCCUS (HYDATID DISEASE)

Echinococcal infection, also called hydatid disease, is a parasitic disease due to echinococcal tapeworms including *Echinococcus granulosus* or *E. multilocularis* in humans. Echinococcus is endemic in the Mediterranean or other parts of the world in sheep rearing economies but is uncommon in the United States. The liver is most commonly affected by *E. granulosus*. Dogs are the definitive host and the life cycle of the organism is such that when the canine host ingests infected viscera (from sheep or cattle) scoleces released in the intestine develop into adult worms. Humans, an intermediate host, acquire echinococcal eggs by ingestion of contaminated foods or with infected animals. The echinococcal egg is digested in the duodenum and yields an embryo (oncospheres). Embryos invade the intestinal wall and reach the liver via the portal circulation. Surviving embryos lodge in the hepatic capillaries and develop into hydatid cysts. Though the liver is the most common location of hydatid cysts (50% to 75% of cases) the lungs can also be affected (25% of cases). *E. granulosus* and *E. vogeli* cause liver cysts while *E. multilocularis* is associated with alveolar disease.^{12,16,17,18}

Figure 58-4. Amebic abscesses of the liver. The cut surface of the liver shows multiple abscesses containing “anchovy paste” material. (Reproduced with permission from Rubin E, Farber JL. *Pathology*. 3rd ed. Philadelphia, PA: Lippincott Williams & Wilkins; 1999.)

Liver involvement with echinococcal cyst can lead to venous obstruction, portal hypertension, sepsis, and cholangitis. Hydatid cysts are fluid filled, round, and contain three layers of host tissue: an outer 2- to 4-mm-thick fibrous pericyst composed of compressed and fibrotic liver tissue, a 2-mm-thick middle anuclear hyaline layer or ectocyst, and an internal germinal layer or endocyst derived from the parasites. As the cyst matures, invagination of the germinal layer leads to development of daughter cysts in the periphery (Fig. 58-5). Calcifications are frequently observed radiographically in both viable and nonviable cysts.^{12,17,18}

Cysts may grow at an annual rate of around 1 to 3 cm/year. Enlarging cysts can cause symptoms of abdominal pain, biliary obstruction, and jaundice, or less commonly portal hypertension. Masses may be palpable clinically on examination. Involvement of the biliary tree is variable. Biliary findings result due to communication between the pericyst and the bile ducts or due to rupture of the cyst into the biliary tree. Fistulous communication between the cyst and the biliary tract may result in superinfection of the cyst, cholangitis, and biliary obstruction. This bacterial contamination occurs in around 25% of cases. Occasionally, cysts may rupture into the peritoneal cavity causing abdominal pain and anaphylaxis. Multiple intra-abdominal cysts may develop due to intraperitoneal leakage. Hepatic hydatid cysts may perforate the diaphragm and lead to empyema, biliary-bronchial fistula, or pericardial collection.¹⁹

Laboratory tests may be normal or reveal biliary obstruction, and eosinophilia is frequently present. Serologic ELISA-based screening tests are associated with high false-positive and negative rates. Confirmatory electrophoresis when available has a higher accuracy rate. Hydatid cysts have a stereotypic appearance on radiographic studies. US imaging may show daughter cysts, a calcified rim, and the so-called water lily sign of the curved bands of the delaminated endocyst. CT scan shows a hypoattenuating lesion with daughter cysts (75%) and a calcified rim (50%). MRI often well displays daughter cysts, pericyst, and the “hydatid sand” of free scoleces. ERCP may be helpful in cases involving the biliary tree.^{12,16}

Figure 58-5. A partly opened hepatic hydatid cyst. Brood capsule and daughter cysts are visible in the cavity. (Reproduced with permission from Kean BH, Sun T, Ellsworth RM. *Color Atlas/Text of Ophthalmic Parasitology*. New York: Igaku-Shoin; 1991:188.)

2 Open surgical resection is the treatment of choice for symptomatic or complicated hydatid cysts

(Fig. 58-6). Surgical extirpation aims to remove the cyst intact without spillage of cyst contents. Alternatively, some have described aspiration of cyst contents prior to resection to minimize the result of any cyst spillage. After aspiration injection with ethyl alcohol or 20% sterile saline is undertaken to kill remaining scoleces. In cases where the aspirate is bilious and a communication with the biliary tree is thus suspected the cyst should be resected without alcohol injection to prevent the occurrence of sclerosing cholangitis. Laparoscopic resection and percutaneous aspiration techniques have been reported, especially in conjunction with albendazole. Albendazole should be started 1 week prior to surgery and generally continued for at least 4 weeks postoperatively. It is poorly absorbed and should be given with a high-fat meal to increase bioavailability (15 mg/kg/day up to maximum of 400 mg twice daily). Mebendazole may be used as an alternative therapy but is less well absorbed. Postoperative morbidity and mortality are low following resection but not zero and recurrence after surgery is reported from 2% to 25%, and is associated with residual cysts or intraoperative spillage of cyst contents.¹⁶⁻²³

SCHISTOSOMA

Schistosoma mansoni, *S. japonicum*, *S. haematobium*, and *S. mekongi* are species of trematode fluke that infect humans in endemic areas or visitors to these sites. Liver disease is especially severe with *S. mansoni*, *S. japonicum*, and *S. mekongi*. The life cycle of *Schistosoma* species alternates between sexual reproduction in humans and asexual multiplication in water snails. Cercariae enter the human host by penetrating the skin. An irritating maculopapular rash that lasts for several days is an early manifestation of infection. Schistosomes live in the intestinal lumen and eggs reach the liver via the portal circulation where they cause an inflammatory reaction.^{17,18,24}

Infection in the liver is characterized by the presence of inflammatory granuloma surrounding schistosomal eggs. Acute schistosomiasis is seen typically in nonimmune visitors to endemic areas and presents as hepatomegaly and severe splenomegaly, often in children and adolescents. Severe cases with high egg infestation can lead to widespread hepatic necrosis and death. In contrast, chronic schistosomiasis is seen in young and middle-aged adults. It is usually asymptomatic until manifestations of portal hypertension declare themselves, such as variceal hemorrhage. Patients will typically present with hepatosplenomegaly, no ascites, and preserved synthetic function due to the presinusoidal nature of the condition. Hepatocellular carcinoma (HCC), colon cancer, and follicular lymphoma of the spleen have been reported in association with hepatic schistosomiasis.^{12,17,18,25,26}

Diagnosis is typically made via the presence of schistosomal eggs in the stool (Kato-Katz smears), epidemiologic data, and biochemical or serologic findings. Typical laboratory features include eosinophilia and elevated alkaline phosphatase. Serum transaminases are typically normal. ELISA serum antibody tests are highly sensitive. Biopsy will show prominent granuloma formation and severe portal fibrosis (Fig. 58-7). Imaging studies are not typically useful in diagnosis of acute infection. In chronic cases US may show portal vein wall thickening. Hypertrophy of the left lobe, splenomegaly, and engorged venous collaterals may all be observed as well. CT may show fibrosis around portal vein branches as well presenting as low attenuation rings through the liver parenchyma.

Figure 58-7. Hepatic schistosomiasis. A hepatic granuloma surrounds a degenerating egg of *Schistosoma mansoni*. (Reproduced with permission from Rubin E, Farber JL. *Pathology*. 3rd ed. Philadelphia, PA: Lippincott Williams & Wilkins; 1999.)

Preferred treatment of schistosomiasis is praziquantel, with cure efficacy around 90%. Treated patients should also undergo evaluation and management of any esophageal varices that may have developed.^{17,18}

VIRAL HEPATITIDES

3 Viral hepatitis represents an important cause of chronic liver disease, cirrhosis, and hepatocellular cancer. Infection is pandemic in the United States and worldwide. Hepatitis C has become the most common indication for liver transplant in the United States and its recurrence has been the most common cause for graft loss after transplant. Liver transplant for hepatitis B has shown greatly improved results in recent years due to improved antiviral treatment. Hepatitis C is now following the same trajectory with the advent of effective antivirals.

The mechanism of liver injury is largely a host inflammatory response to virus. [Table 58-1](#) summarizes current understanding of the characteristics of the five viruses most commonly associated with clinical hepatitis, their modes of transmission, and the consequences of infection.

GB Virus, formerly known as hepatitis G virus (HGV) does not appear to be deleterious to the liver. Other viral infections can produce acute hepatitis, particularly in immunocompromised hosts (e.g., Epstein–Barr virus, cytomegalovirus, herpes simplex virus, and varicella zoster virus). In some cases the hepatitis caused by these viruses in association with systemic symptoms can be severe and liver involvement may be the dominant manifestation of the patient’s illness.

HEPATITIS A VIRUS

Molecular Structure

Hepatitis A virus (HAV) was identified in 1973²⁷ and belongs to the Picornaviridae family, genus Hepatovirus. Four distinct genotypes have been identified and all four genotypes belong to a single serotype.²⁸ HAV is a single-stranded RNA virus that is 27 nm in diameter and is nonenveloped. The viral genome is 7,474 nucleotides in length and is divided into 5- and 3-in untranslated regions and a single long open reading frame that encodes a 2,227 amino acid polypeptide. Upon processing this peptide yields four structural and seven nonstructural proteins.

Epidemiology/Risk Factors for Transmission

Hepatitis A has been long known (epidemic jaundice, catarrhal jaundice, campaign jaundice) and continues to occur worldwide. The incidence in the United States has declined with effective vaccination but remains around 1.2 per 100,000.²⁹

The major mode of transmission is fecal–oral and it is more common in lower socioeconomic areas where sanitation is poor. Common risk factors in the United States are international travel, especially to Mexico or Central/South America; household contact with an infected family member; homosexual activity in men; ingestion of contaminated foods (shellfish, green onions, frozen strawberries) or waterborne outbreaks; children in daycare centers; and injection drug use.³⁰ Humans are the only host for HAV and the liver is the only affected tissue.

Clinical Features

Hepatitis A infection almost universally results in an acute, self-limited illness and can produce either icteric or anicteric syndromes (Fig. 58-8). The incubation period is 28 days. The anicteric prodrome lasts from 2 days to 3 weeks and typically consists of fatigue, malaise, nausea, vomiting, anorexia, fever, and right upper quadrant pain. The diagnosis may be missed in cases without jaundice. In cases where jaundice becomes manifest, it persists for 1 to 6 weeks. Transaminase levels are typically above 1,000 IU/mL, serum bilirubin above 10 mg/dL, and alkaline phosphatase values are elevated as well. Serum IgM antibodies are detected in 95% of patients and are the gold standard of diagnosis. IgG antibodies become elevated as jaundice subsides and may persist for years.

Table 58-1 Classification of Viral Hepatitis

The Viral Hepatitis					
Virus	Hep A Picornavirus (RNA)	Hep B Hepadnavirus (DNA)	Hep C Flavivirus (RNA)	Hep D Viroid (RNA)	Hep E Calicivirus (RNA)
Transmission	Fecal–oral	Parenteral	Parenteral	Parenteral	Fecal–oral
Acute disease	Common	Common	Uncommon	Common	Yes
Evolution to chronic disease	Never	Infrequent in adults	Frequent (70%)	Yes	Described in organ transplant recipients
New cases/year	180,000	180,000	40,000	Unknown, found in approximately 5% of cases of HBV infection	300
# Infected (US)	—	1,250,000	4,000,000		Unknown, uncommon
Worldwide	—	350,000,000	170,000,000		
Treatment	None	Lamivudine Adefovir Entecavir	Interferon + Ribavirin	Treatment of HBV	Mainly sanitary preventative
Prophylaxis	Vaccine and Ig	Vaccine and Ig	None	Vaccinate against HBV	In development
Fulminant failure	Rare	Yes	Never	With HBV, as coinfection or superinfection	Especially in pregnant women

HBV, hepatitis B virus; Hep, hepatitis; Ig, immunoglobulin.

HAV leads to fulminant liver failure in 0.01% to 0.35% of cases of acute HAV infection. This rare event mostly occurs in patients with underlying liver disease, especially chronic hepatitis C infection and less commonly hepatitis B infection or alcoholic liver disease. The risk of fulminant failure is also higher in people over 40 years of age, intravenous drug abusers, men who have sex with men, and in inhabitants of endemic areas.³¹

Figure 58-8. Clinical course of hepatitis A infection.

Treatment

Most patients with HAV infection recover with supportive care; approximately 20% require hospitalization in large outbreaks. Infection control measures such as hand washing and isolation should be a top priority to prevent spread of virus. Fecal shedding of virus occurs even prior to onset of symptoms and jaundice. Spontaneous recovery and survival even in cases of acute liver failure (ALF) may be as high as 50%. Liver transplantation is indicated in cases in which recovery seems unlikely. Recurrence of HAV in the allograft may be encountered and administration of immunoglobulin may be beneficial in such instances.^{31,32}

A formalin-inactivated HAV vaccine is safe and effective in almost all recipients after two doses. Vaccination is recommended by the CDC for children 2 years of age or older in states or countries with high rates of infection (20 or more cases per year per 100,000 population) as well as in individuals at high risk such as persons infected with hepatitis B or C. Immune globulin administered within the first 14 days of exposure prevents disease in more than 85% of cases. Close contacts of patients with recent onset of the illness, people exposed to contaminated foods, and selected travelers to endemic areas benefit the most.³³

HEPATITIS B VIRUS

Molecular Structure

Hepatitis B Virus (HBV) is a DNA virus that belongs to the hepadnavirus family. It is the smallest DNA virus with the ability to infect humans. HBV virions are 40 to 42 nm in diameter, with a double shell and an outer lipoprotein envelope. The viral nucleocapsid, or core, contains a 3.2-kb partially duplex DNA and a polymerase. Replication resembles that of retroviruses, in which the viral DNA polymerase acts as a reverse transcriptase. The HBV polymerase lacks proofreading activity. This is associated with an estimated 10^5 to 10^6 mutations per nucleotide per year and the resultant development of mutant forms of the virus.³⁴⁻³⁶

Epidemiology/Risk Factors for Transmission

It is estimated that over 350 million people worldwide are infected by HBV. In the developing world, perinatal infection is the most common mode of transmission. In the United States, transmission is primarily sexual as the virus is present in semen and vaginal fluids in addition to blood. Infection from intravenous drug use and occupational infections due to percutaneous exposure also occur. There are no known animal reservoirs or evidence that insects are involved in transmission of HBV. The hepatitis B virus replicates mainly in hepatocytes but is not itself cytotoxic. Liver injury is due to the resultant host immune response.

Clinical Features

The incubation period for HBV is 8 weeks. The presence of serum hepatitis B surface antigen (HBsAg) may precede jaundice. Acute infection is associated with detectable serum HBV DNA, hepatitis B early antigen (HBeAg), and IgM to hepatitis B core. HBeAg is a useful marker of viral replication except in patients with mutant viruses where it may be undetectable despite active replication (Fig. 58-9). In such cases detection of HBV DNA is diagnostic. Serum anti-HBc IgM becomes detectable with the onset of jaundice. In most patients, when HBV does not develop into chronic hepatitis, anti-HBc IgM becomes undetectable after 6 months. On occasion, however, it may persist for years after the acute infection or may recur as an amnestic phenomenon in reactivating chronic hepatitis B, thus limiting its usefulness as a marker of acute HBV infection.

Although HBV accounts for 40% of ALF in developing countries, it is estimated that the incidence in the United States is about 10%. Hepatitis B becomes fulminant in about 1% of acute infections. Women, elderly individuals, and those who sustain superinfection with another virus (such as HCV) seem to be at greater risk. Furthermore, the risk of ALF seems to be proportional to antibody titers of HBcAg and HBsAg. Some cases of ALF may be due to reactivation of HBV in patients with chronic infection. In cases of reactivation, reappearance of HBc IgM antibodies aids in the diagnosis. Spontaneous survival after HBV ALF is in the 25% range.^{37,38}

Most patients with acute HBV infection in the Western world recover completely. Approximately 25% of these patients will develop jaundice but do not become HBV carriers. They will usually retain HBcAb and HBsAb markers with no detectable HBsAg or HBV DNA. Approximately 10% of Western adults with HBV infection do progress to become chronic carriers, as determined by the presence of HBsAg in serum for more than 6 months (Fig. 58-10). Most HBV carriers have a benign state with HBV DNA integrating into their native genome. The remainder of HBV carriers develop ongoing liver injury and usually have detectable HBeAg or HBV DNA and have free episomal HBV sequences in addition to the ones integrated into their native genomes.

Figure 58-9. Clinical course of acute hepatitis B infection.

In Western Europe and North America the prevalence of chronic infection is less than 1% but ranges between 10% and 20% in endemic areas including southeast Asia, China, and sub-Saharan Africa. It is estimated that there 1 million deaths each year as a result of cirrhosis and HCC associated with chronic HBV worldwide.

Treatment

Primary prevention by means of vaccination constitutes the best treatment approach for HBV infection. Individuals at high risk include health care workers, visitors to highly endemic areas, men who have sex with men, sex workers, and intravenous drug users. The hepatitis B vaccine is given as a series of three intramuscular doses and has almost 100% efficacy among immunocompetent persons. Hepatitis B immune globulin has a reported efficacy of 90% in the prevention of newborn infections and approximately 75% in cases of needle sticks or sexual infections in people exposed to the virus with no prior immunity. It is administered as soon as possible after exposure together with the first dose of the hepatitis B vaccine series.

Figure 58-10. Clinical course of chronic hepatitis B. **A:** A benign chronic carrier has continued production of hepatitis B surface antigen but there is an absence of serum markers of viral replication. **B:** A pattern of continuing liver injury and serum markers of active viral replication.

Therapy is usually directed at HBeAg-positive cases that have an increased risk of cirrhosis and HCC. HBeAg-negative patients with high viral load may also benefit from treatment. Effectively controlled infection is determined by loss of HBsAg and absent viremia by PCR on antiviral treatment. The endpoint of treatment is loss of HBeAg and seroconversion to detectable HBeAb. In clinical trials about half of patients achieved this endpoint after 5 years of treatment but many patients will require a longer duration of therapy, in some cases, lifelong. Patients with chronic hepatitis B and cirrhosis or advanced fibrosis showed a reduction in the risk of HCC after continuous treatment with lamivudine.^{35,39} Lamivudine is an orally effective antiviral agent that competitively inhibits the DNA polymerase. Its administration is associated with a more rapid seroconversion to HBeAg-positive status, a more rapid loss of HBeAg, improved aminotransferase levels, and a 3 to 4 log reduction in circulating levels of HBV

DNA in the first 3 months of therapy. It is also associated with improved liver histologic findings in cases of chronic hepatitis.

Agents available to treat hepatitis B include interferon (IFN), lamivudine, entecavir, adefovir, telbivudine, and tenofovir. The most widely used, well-tolerated, and effective agents include the nucleoside analogues lamivudine, entecavir, and tenofovir. Lamivudine is effective and low cost; its major limitation is the development of drug resistance. Entecavir and tenofovir are active against lamivudine-resistant variants and can be considered for first-line treatment in individuals if cost is not a limiting factor. Both lamivudine and tenofovir are active against human immunodeficiency virus (HIV), so these agents are preferred in individuals coinfecting with HIV and HBV.

Liver transplantation is the treatment of choice in patients with hepatic failure. Recurrence of viral infection in the allograft can be as high as 80% in HBeAg-positive cases where no postoperative prophylaxis is administered. The combination of lamivudine and hepatitis B immune globulin posttransplantation reduced the reinfection rate to less than 10% and increased the 5-year survival rate to 80%.³⁵ Other posttransplant pharmacologic regimens are currently being examined.⁴⁰

HEPATITIS C VIRUS

Molecular Structure

Hepatitis C virus (HCV) is a lipid enveloped, 9.4-kb, single-stranded RNA virus of the family Flaviviridae, genus Hepacivirus.⁴¹ Six genotypes have been identified, which differ from one another by as much as 30% at the sequence level. Quasispecies within genotypes demonstrate further genetic heterogeneity and reflect the high rate of mutation seen in viral replication. Over 70% of US cases are due to genotype 1 virus.

Epidemiology/Risk Factors for Transmission

There are more than 185 million individuals infected with HCV worldwide, translating to a global prevalence of 2.8%. In the United States, there are an estimated 3.6 million HCV-infected individuals, approximately 1% of the population, but this is likely an underestimate as these estimates do not include high-risk homeless or incarcerated populations.^{42,43}

Figure 58-11. Clinical course in acute hepatitis C.

The most commonly identified risk factors are exposure to blood or blood products prior to 1992 and intravenous drug use. Other risk factors include intranasal drug use due to mucosal exposure to blood on drug paraphernalia, anal intercourse in men who have sex with men due to blood-mucosal exposure, occupational exposure, hemodialysis, tattooing, and perinatal transmission. In the United States, more than 80% of infections have been identified in adults born between 1945 and 1965.⁴¹ Due to this observation, the CDC now recommends screening all individuals in this birth cohort irrespective of reported risk factors.

Clinical Features

The usual incubation period of HCV is 5 to 10 weeks. Most acutely infected patients are asymptomatic and therefore the infection goes unappreciated. Initial laboratory findings after infection include elevated ALT levels (500 to 1,000 IU/mL) and high HCV RNA titers (Fig. 58-11). HCV clearance is spontaneous in about 15% to 20% of individuals following primary infection. Hepatitis C infection by

itself is almost never associated with ALF. Liver damage in the setting of chronic infection is due to host immune response rather than viral hepatotoxicity. Ongoing chronic hepatic injury leads to progressive fibrosis and cirrhosis which typically occurs over decades, in most cases undetected until the appearance of overt liver failure (Fig. 58-12). The incidence of hepatic decompensation (variceal hemorrhage, ascites, jaundice, encephalopathy) in the setting of cirrhosis is approximately 5% per year. Hepatitis C cirrhosis is strongly associated with the development of HCC. Extrahepatic manifestations of hepatitis C include membranoproliferative glomerulonephritis, cryoglobulinemia, diabetes, porphyria cutanea tarda, lichen planus, vitiligo, and non-Hodgkin lymphoma.⁴⁴

Figure 58-12. Clinical course in chronic hepatitis C.

The diagnosis of chronic hepatitis C is based on serologic demonstration of persistent HCV RNA and HCV antibodies. HCV RNA can be detected weeks earlier than antibodies, which typically appear 2 to 8 weeks after the initial infection.

Treatment

With the recent advent of highly effective, well-tolerated antiviral therapy, all individuals who develop hepatitis C should be offered treatment. The goal of treatment is a sustained virologic response or absence of HCV RNA in serum 3 to 6 months after stopping treatment. Therefore, unlike HBV, therapy in HCV is ideally curative.

In the past, the mainstay of therapy included IFN alpha combined with ribavirin (RBV) given for 48 weeks. This combination had poor tolerability and poor efficacy, with SVR rates for genotype 1 infections ranging from 35% to 45% depending on stage of disease and patient characteristics. In 2011, the first directly acting antivirals (DAAs) designed to specifically inhibit HCV proteins became available. Inhibitors of the HCV NS3A protease, boceprevir and telaprevir, were the first to be introduced but they still had to be given in combination with IFN and RBV. These first PI-based regimens increased SVR rates up to about 60% to 70%, but they compounded the toxicities of IFN and RBV, with high rates of serious adverse events including death. In 2013, more effective antivirals were introduced which allowed for IFN-free, ribavirin-free treatment regimens. With 12 to 24 weeks of treatment, DAA combinations have SVR rates between 95% and 100% and very few side effects. New antivirals include second-generation protease inhibitors nucleotide and nonnucleotide analog inhibitors of the HCV NS5B polymerase and inhibitors of the HCV NS5A replication complex. Over the next several years, many additional DAAs are expected to be approved. Determining the optimal combination for treatment will depend on factors such as genotype, comorbidities, and drug-drug interactions.

4 Transplantation is the treatment of choice in cases of irreversible decompensated cirrhosis due to HCV and in cases of HCC due to HCV. Thus, HCV has become the most common indication for liver transplantation in the United States and many countries worldwide. In many cases, treatment cannot completely reverse all hepatic damage from HCV and risk of HCC remains. Therefore, even if access to HCV diagnosis and effective treatment is optimal, the need for liver transplantation due to HCV is expected to continue for decades.

HEPATITIS D VIRUS

Molecular Structure

The hepatitis D virus (HDV), or delta agent, is an incomplete RNA virus that requires the presence of

HBV for viral assembly and propagation. The only enzymatic activity of HDV is a ribozyme that cleaves circular RNA and makes it linear. The HDV genome is a 1,680 nucleotide, single-stranded circular RNA.⁴⁵ Eight genotypes have been proposed.⁴⁶ A single HDV antigen is encoded, it is a structural component of the virion, and a lipoprotein envelope is provided by HBV.

Epidemiology/Risk Factors for Transmission

HDV is found in approximately 5% of HBV carriers. Due to its dependence on HBV, HDV always occurs in association with HBV infection. Transmission is similar to that of HBV, via parenteral or sexual exposure to blood or body fluids. HDV hepatitis occurs only in HBsAg- positive patients.

Figure 58-13. Synchronous infection with hepatitis B virus and hepatitis D virus.

Clinical Features

Acute infection is diagnosed by the presence of anti-HDV IgM. Anti-HBc IgM distinguishes coinfection from superinfection (Figs. 58-13 and 58-14). The diagnosis in patients with chronic liver disease is made by the presence of HBsAg and antibodies against HDV in the serum and confirmed by the presence of HDV antigen in the liver or HDV RNA in the serum (Fig. 58-15). ALF is seen with both coinfection (HDV and HBV simultaneously infects the host) and superinfection (HDV infects a host already infected with HBV). Superinfection seems to be associated with a higher mortality rate. Chronic HDV and HBV infection may coexist. Cirrhosis is observed in at least two-thirds of patients and occurs at a younger age than in patients infected with HBV alone.^{47,48}

Treatment

Treatment and prevention of HDV are associated with that of hepatitis B, with which it always coexists. Vaccination for HBV is contributing to the decline in the incidence of HDV. Alpha IFN is the only currently available treatment for chronic HDV.

Figure 58-14. Superinfection of chronic hepatitis B carrier with hepatitis D.

Figure 58-15. Clinical course of chronic hepatitis D infection.

HEPATITIS E VIRUS

Molecular Structure

Hepatitis E virus (HEV) is a nonenveloped single-stranded RNA virus. It is 30 nm in diameter and is most similar to other viruses of the Caliciviridae family. There are three large open reading frames, the first of which is 1,693 codons and codes for nonstructural proteins. The second is 660 codons and encodes structural proteins. The third is smaller and of undetermined function. There are thought to be four genotypes.⁴⁹

Epidemiology/Risk Factors for Transmission

Hepatitis E is enterically transmitted and is epidemiologically similar to HAV. Infection has been prominently observed in Asia, Africa, the Middle East, and Central America. In addition, vertical transmission from mother to child has been documented and can be a source of perinatal morbidity and mortality.

Clinical Features

HEV generally causes a self-limited acute infection, although chronic infection has been described in organ transplant recipients. The incubation period usually lasts 3 to 8 weeks, and most individuals recover without chronic findings after a transient cholestatic episode (Fig. 58-16). However, young adults and women in late stages of pregnancy may develop fulminant cases of hepatitis E. Mortality from HEV is 0.5% to 4% in the general population but up to 20% in pregnant women.⁵⁰⁻⁵² Diagnosis is aided by detection of serum or fecal genomes during the acute phase. In addition, one can demonstrate anti-HEV IgM or IgG in follow-up.

Figure 58-16. Clinical course of chronic hepatitis E infection. (Reproduced with permission from Expert Reviews in Molecular Medicine: (99)00129—5 h.htm; 6 December 1999.)

Treatment

Infection in most cases is self-limited; however, in immunosuppressed organ transplant patients HEV can

cause persistent hepatitis and cirrhosis. There are no randomized controlled trials evaluating treatment options, but there are observational studies that report benefit with ribavirin treatment in organ transplant recipients.⁵³

CYTOMEGALOVIRUS

Cytomegalovirus (CMV) is a member of the Beta-Herpesviridae family. It is usually associated with mild hepatitis but may occasionally cause ALF. Transmission can be intrauterine, perinatal, or postnatal; through intimate contact of infected fluids such as blood, saliva, or urine, or through transplanted organs. Infection is lifelong due to the latency of the virus and can be detected in up to 70% of individuals in US cities. Organ injury can occur as a result of primary infection or due to reactivation of latent infection. In the neonatal period congenital infection can be severe and fatal. In immunocompetent adults liver dysfunction tends to be found in association with CMV mononucleosis. In immunosuppressed adults, infection leads to liver dysfunction with jaundice and at times liver failure. Acalculous cholecystitis is another presentation.^{31,54,55} CMV antigenemia and PCR to detect CMV DNA have made diagnosis rapid. Liver biopsy is important to establish the diagnosis of hepatitis. Pathologic examination shows inflammation and injury ranging from fatty changes to necrosis to fibrosis. Giant multinucleated cells and large nuclear inclusions can be encountered in hepatocytes and bile duct epithelial cells.^{31,54,55}

First-line treatment is with ganciclovir or valganciclovir. Second-line agents for cases of resistant CMV include foscarnet, or cidofovir. Anti-CMV immune globulin can be used as an adjunct.⁵⁶

EPSTEIN–BARR VIRUS

Epstein–Barr virus (EBV) is a DNA virus and member of the Herpesviridae family. Infection persists for life due to latency of the virus and it is usually transmitted by close personal or intimate contact via oral secretions. Some degree of liver involvement is encountered in almost all cases of primary EBV also known as mononucleosis. It is usually mild without major clinical manifestations and resolves spontaneously. The presence of jaundice may reflect either more severe hepatitis or an associated hemolytic anemia. Occasional cases of ALF have been reported in both the immunocompetent and immunocompromised population. Leukocytosis is usually present, with the presence of atypical lymphocytes being a hallmark. Detection of heterophile antibodies, or the “monospot test” is highly specific but somewhat insensitive with false-negative rates as high as 25% early in infection. If acute EBV is suspected and heterophile antibodies are not detected EBV-specific antibody testing can be used which are highly sensitive and specific. Treatment is supportive. Acyclovir has activity against EBV but clinical trials have not shown a clear benefit to use of acyclovir. Liver transplant has been reported in rare life-threatening situations.^{54,56–58}

HERPES SIMPLEX VIRUS

The prevalence of antibodies to HSV-1 is around 75% in most populations and around 20% to HSV-2. Fulminant hepatitis is a rare complication of HSV infection; those at risk include the neonates, the immunocompromised, the malnourished, and the pregnant adults. Fulminant hepatitis is usually associated with multiorgan failure and is associated with a high mortality rate. Clinical features include high fever, anorexia with nausea, abdominal pain, leucopenia, and coagulopathy. Liver biopsy is important in establishing the diagnosis. Microscopic examination shows diffuse eosinophilic intranuclear inclusion bodies, multinucleated cells, widespread necrosis, and inflammation. Cowdry A-type intranuclear inclusions are typical. Confirmation is by PCR. Approved antivirals include acyclovir, famciclovir, and valacyclovir. Treatment with intravenous acyclovir should be initiated prior to confirmation of etiology given that progression of disease is extremely rapid and lethal. Liver transplantation can be considered even in cases of disseminated disease.^{54–56}

VARICELLA ZOSTER VIRUS

Herpesvirus varicella (also called varicella zoster virus [VZV]) is usually associated with mild hepatitis

but may occasionally cause ALF. Up to one-fourth of children with varicella (chickenpox) may exhibit temporary mild biochemical liver abnormalities. Reye syndrome may be encountered during the convalescence period especially in those who receive aspirin. In such cases mortality can be as high as 30%. Fulminant fatal hepatic failure is uncommon, but generally affects immunocompromised patients. Confirmation of the diagnosis can be achieved by isolation of the virus from affected tissues. Varicella zoster immune globulin should be considered after exposure to the virus in immunocompromised or pregnant patients who lack immunity to VZV. Current therapies for VZV infection in immunocompetent and immunocompromised hosts include acyclovir, valacyclovir, and famciclovir. CDC guidelines should be followed for infection control.^{31,54,56}

ACUTE LIVER FAILURE

Definition

ALF is an uncommon but serious condition with approximately 2,000 cases per year in the United States⁵⁹ and which carries a high mortality rate of 60% to 80%.⁶⁰ It is characterized by rapid deterioration of liver function as well as development of hepatic encephalopathy in an individual with no previous liver disease. Currently, emergency liver transplantation is the only therapeutic option available, and the King's College Criteria are widely accepted as the standard of guidance. ALF is responsible for about 5% of all liver related deaths and approximately 5% of all liver transplants are performed for this indication.⁶¹

The most widely accepted definition includes an international normalized ratio (INR) greater than 1.5 and any degree of mental alteration (encephalopathy) in a patient without pre-existing liver disease and with an illness of less than 26 weeks' duration. Patients with Wilson disease, vertically acquired hepatitis B, or autoimmune hepatitis can be considered to have ALF if the disease process has started within 26 weeks.⁶² Although the literature suggests hyperacute (<7 days) and subacute (>21 days but <26 weeks) forms, they do not have prognostic significance except in the case of hyperacute failure due to acetaminophen toxicity which may carry a better prognosis.⁶³

Diagnosis

A high index of suspicion is vital in early recognition of the disease process. Patients with evidence of moderate to severe hepatitis and any degree of encephalopathy require hospitalization since the process may proceed to death rapidly.⁶⁴ Likewise early transfer to an intensive care unit (ICU) setting in a liver transplant center is important (especially before the onset of grade III or IV encephalopathy) since worsening encephalopathy can potentially hamper transportation efforts due to concerns over increased intracranial pressure (ICP). Detailed history taking from accompanying persons including medications and herbal supplements taken and recent social history is essential. Stigmata of chronic liver disease should be assayed during the physical examination although jaundice may be a relatively late manifestation of the disease process. The initial recommended laboratory testing is listed in [Table 58-2](#).⁶⁴ Lastly, transjugular liver biopsy can be considered as part of the initial workup to rule out neoplastic infiltration or HSV/herpes zoster virus (HZV) infection, although it is not always necessary, beneficial, or safe in all cases.⁶³

Table 58-2 Management in Acute Liver Failure: Initial Laboratory Evaluations

Serum chemistries Sodium, potassium, chloride, bicarbonate, calcium, magnesium, phosphate, glucose, BUN, creatinine, amylase, lipase
Hepatic panel AST, ALT, alkaline phosphatase, total bilirubin, albumin
Prothrombin time/INR
Complete blood count
Arterial blood gas, lactate, ammonia
Toxicology screen
Viral hepatitis serologies Anti-HAV IgM, Hep B surface Ag, Anti-HBV core IgM, anti-HCV, anti-HEV IgM (if indicated)
Anti-VZV IgM, Anti-HSV IgM
Autoimmune markers ANA, ASMA, IgG levels, SPEP
Pregnancy test
Serum ceruloplasmin level and 24-hr urine copper collection (if Wilson disease is suspected)

Ag, antigen; ALT, alanine aminotransferase; ANA, antinuclear antibody; ASMA, anti-smooth muscle antibody; AST, aspartate aminotransferase; BUN, blood urea nitrogen; HAV, hepatitis A virus; HBV, hepatitis B virus; HCV, hepatitis C virus; HEV, hepatitis E virus; HSV, herpes simplex virus; IgM, immunoglobulin M; INR, international normalized ratio; SPEP, serum protein electrophoresis; VZV, varicella zoster virus.

Etiology

Etiology is important in ALF in that it may dictate administration of appropriate antidotes or to better anticipate prognosis and the potential need for liver transplantation.⁶⁵ Etiology seems to have geographic variation. In the United States, the most common reported cause of ALF is acetaminophen overdose (45% of cases), followed by unknown (15%), drug related (10%), hepatitis B virus (7%), autoimmune hepatitis (5%), and Wilson disease (2%).⁶⁶ In the United Kingdom, acetaminophen toxicity is reported in over 60% of cases, whereas in France, frequency of reported etiologies is viral due to hepatitis A and B (30%), acetaminophen (20%), other drug over dose (18%), and unknown (17%).^{63,67}

Drug-induced Liver injury. Intrinsic hepatotoxins are usually dose dependent, while idiosyncratic responses are dose independent. Acetaminophen toxicity is dose dependent with serious injury seen with levels greater than 10 g/day but sometimes reported in cases with levels as low as 3 to 4 g/day range. Glutathione becomes depleted with excess free NAPQI (a toxic byproduct of acetaminophen) reacting with hepatocytes, causing liver injury.⁶⁵ In the presence of poor nutritional state or alcoholism, glutathione levels are chronically depleted further contributing to toxicity. Stevens–Johnson syndrome caused by phenytoin, amoxicillin-clavulanate, carbamazepine, or halothane, is a form of hypersensitivity idiosyncratic reaction, while isoniazid, valproate, and amiodarone mainly cause metabolic idiosyncratic reactions.

Viral Hepatitis. In those with HAV, ALF occurs around 0.5% of the time; age over 40 and other pre-existing liver disease represent increased risk. In those with HBV, ALF occurs in 1.5% of cases. ALF may occur due to new infection or reactivation of a chronic carrier state. HDV coinfection and HEV should be suspected in endemic areas. VZV, HSV, and CMV are other rare viral causes of ALF.⁶⁵

Other. Acute Budd–Chiari syndrome, veno-occlusive disease, medications and herbs, and malignancies involving the liver (i.e., lymphoma, angiosarcoma) are less common causes of ALF.⁶⁴ Acute fatty liver of pregnancy (AFLP), and HELLP (Hemolysis, Elevated liver enzymes, Low platelets) are important diagnoses to be considered among pregnant women presenting with manifestations of ALF. AFLP occurs during the third trimester of pregnancy due to deficiencies in 3-hydroxyacyl-CoA dehydrogenase in both the mother and fetus with rapid deposition of triglycerides and free fatty acids into hepatocytes. HELLP also occurs in the third trimester or immediately postpartum. Autoimmune hepatitis (AIH) can present acutely with absence of autoimmune markers, where the diagnosis is made by exclusion and transjugular liver biopsy. In the fulminant form of Wilson disease, chelator treatment is ineffective and diagnosis is usually based on familial history of liver disease in a young adult with Coombs-negative hemolysis and low serum alkaline phosphatase or uric acid levels. Kayser–Fleischer rings are present in 50% of patients.⁶² Diagnosis is usually confirmed by hepatic copper content greater than 250 µg/g in patients homozygous for Wilson disease, and the rate of urinary excretion may exceed 100 µg/24 hours.⁶⁸ Heat stroke, mushroom ingestion, EBV, and parvovirus B19 are rare causes of ALF.⁶³

Clinical Features, Management, and Treatment

Acute liver injury in the absence of hepatic encephalopathy is a reversible entity unless an underlying

chronic liver disease is present. Altered mental status accompanied by jaundice and elevated serum transaminases and prothrombin time is the hallmark of presentation. Rapid loss of liver mass can lead to multisystem organ failure and death.⁶⁴ Encephalopathy may be accompanied by myopathy and neuropathy, loss of vascular tone with hypotension, cardiac dysfunction, acute lung injury, gastrointestinal bleeding, pancreatitis, acute renal failure, and/or disseminated intravascular coagulopathy. Intracranial hypertension is recognized in 50% or greater of patients with stage IV coma. Therefore, neurocritical care with ability to respond to hemodynamic fluctuations becomes an important component of management. Other precepts are maintenance of normoxia, euglycemia, control of seizure, therapeutic hypothermia, osmotic therapy, and judicious hyperventilation.⁶⁹

Initial management includes identification and treatment of infection, titration of intravascular volume expansion, and selection of fluids to minimize cerebral edema. Hypertonic saline may be considered to maintain serum sodium in the mildly hypernatremic range. Norepinephrine is the vasopressor of choice and early initiation of renal replacement therapy is important for tight control of intravascular volume. Mild reduction in blood CO₂ tension can also restore cerebral vasoreactivity and autoregulation.⁶⁹

Advanced cerebral edema is associated with hyperventilation, hypertension, papillary abnormalities, decerebrate posturing, and ultimately uncal herniation and death. Arterial ammonia levels greater than 200 µg/dL may be correlated with herniation.⁶⁴ Although powered controlled trials are still needed to determine the role of intracranial pressure monitoring,⁷⁰ management should aim to keep the cerebral perfusion pressure (mean arterial pressure–intracranial pressure) over 50 mm Hg and the intracranial pressure below 25 mm Hg. Sustained pressures greater than these values for longer than 2 hours usually signifies irreversible brain damage.⁶⁴ Mannitol intravenous bolus doses of 0.5 to 1 g/kg are effective in decreasing cerebral edema by maintaining osmotic diuresis and can be repeated provided serum osmolality does not exceed 320 mOsm/L.⁶² Profound coagulopathy (INR >7) and/or planned invasive procedures warrant correction of coagulopathy with fresh frozen plasma (FFP) in combination with recombinant activate factor VII (rFVIIa).⁶²

Liver Transplantation

Establishing the cause of ALF is an important determination of outcomes following liver transplantation, with the best results achieved with Wilson disease and the worst seen with idiosyncratic drug reactions. Overall survival rates following liver transplantation at 1 year are 20% below those seen for elective transplants performed for chronic disease but are similar to those achieved in patients with chronic disease who go to transplant from the ICU.⁷¹

5 Patients who are at high risk of progression to death should be identified and listed for transplantation in a timely fashion. Likewise, it is also crucial to identify patients who have become too sick to benefit from liver transplant. Relative contraindications to liver transplant include: sustained cerebral hypoperfusion (CPP <40 mm Hg) for longer than 2 hours, high doses of vasopressor, acute respiratory distress syndrome (ARDS) requiring high inspired FiO₂ and elevated PEEP.⁶⁹

Life Support Systems

Various biologic and charcoal-based sorbent systems have been tested to date with no demonstrable clinical impact. Total plasma exchange has been studied retrospectively when used to stabilize patients until a transplant can be obtained or self-regeneration occurs.⁶³ Sorbent systems have shown transient detoxification with no long-term benefits at the expense of worsening coagulopathy. Porcine cell-based and hepatoblastoma-derived extracorporeal systems, the molecular adsorbents recirculating system (MARS),⁷² and the Prometheus system⁷³ are available only for clinical trials and their future in the management of ALF remains uncertain.⁶²

STAGING

Table 58-2 King's College Criteria of Poor Prognostic Indicators

Acetaminophen-induced ALF:
Arterial pH <7.3 irrespective of coma grade
OR all of the following:
INR >6.5, creatinine >3.4 mg/dL (300 µmol/L), grade III/IV encephalopathy

Non-acetaminophen-induced ALF:
INR >6.5
OR any three of the following:
Age <10 or >40, drug toxicity or undetermined etiology, jaundice >7 days before encephalopathy, INR >3.5, bilirubin >17 mg/dL (300 µmol/L)

ALF, acute liver failure; INR, international normalized ratio.

Prognosis

Accurate prognosis in ALF is important to avoid unnecessary liver transplantation, and the traditionally accepted King's College Criteria are most commonly used for this purpose (Table 58-3). Of note is that the Model for End-Stage Liver Disease (MELD) system cannot be applied in ALF.⁶²

ALF due to acetaminophen overdose, hepatitis A, shock liver, or pregnancy-related disease show a 50% or more transplant-free survival, while most other etiologies show only a 25% transplant free survival.⁶² Other proposed but not widely accepted poor prognostic criteria include alpha fetoprotein levels, ratio of factor VIII and V levels, liver histology, and serum phosphate levels.

Recipients who underwent liver transplant for drug induced ALF in the United States from 1987 to 2006 were retrospectively studied and the most common drug groups were identified as acetaminophen, antituberculosis medicines, antiepileptics, and other antibiotics. Patients aged 7 years or younger with antiepileptic toxicity had the highest risk of death following liver transplantation compared to all other groups. Mechanical ventilation and elevated serum creatinine were identified as other predictors of poor survival after transplant.⁷⁴

Chapter 59

Cirrhosis and Portal Hypertension

Michael R. Marvin, Robert M. Cannon, and Jean C. Emond

Key Points

- 1 Although the causes of cirrhosis and the morphologic and histologic changes seen in the liver overlap significantly, oxidative stress leading to chronic injury and inflammation appears to be a common theme.
 - 2 The key mediator in alcohol-induced liver disease is acetaldehyde, which produces numerous deleterious effects on the liver.
 - 3 Nonalcoholic fatty liver disease or nonalcoholic steatohepatitis (NASH) is characterized by infiltration of the liver with fat and is associated with obesity, hyperlipidemia, and noninsulin-dependent diabetes.
 - 4 Viral hepatitis is the most common cause of cirrhosis worldwide, accounting for at least 50% of cases.
 - 5 Budd–Chiari syndrome is a rare disease caused by mechanical obstruction of the hepatic veins owing to obstructing webs or membranes (most commonly in Asia and Africa) or thrombosis secondary to hypercoagulable states and neoplasms (most commonly in the West).
 - 6 Hepatorenal syndrome is a complication of cirrhosis, usually associated with ascites, characterized by progressive renal failure in the absence of intrinsic renal disease.
 - 7 Hepatic encephalopathy is a neuropsychiatric syndrome that occurs in the setting of hepatic disease and is characterized by variable alterations in mental status ranging from deficits detectable only by detailed psychometric tests to confusion, lethargy, and ultimately coma.
 - 8 Portal hypertension is defined as a portal pressure above the normal range of 5 to 8 mm Hg and can be secondary to cirrhosis (hepatic), portal vein thrombosis (presinusoidal), or hepatic venous obstruction (postsinusoidal).
 - 9 The Child–Turcotte–Pugh score is a scoring scale that incorporates clinical and laboratory data as a mean to assess the functional status of the liver, estimate hepatic reserve, and predict morbidity and mortality of liver disease. The model for end-stage liver disease (MELD) score is a highly reliable prognostic marker for cirrhosis, is calculated from standard laboratory tests, and has replaced the Child–Turcotte–Pugh score in liver transplant candidate stratification.
 - 10 The use of the transjugular intrahepatic portosystemic shunt (TIPS) has become first-line therapy for refractory or recurrent bleeding esophageal varices, with 6-month and 1-year patency rates and prevention of rebleeding in 92% and 82% of patients, respectively.
 - 11 Although the surgical interventions for treatment of bleeding varices are divided into three main types – liver transplantation, shunt procedures, and devascularization procedures – the only definitive procedure in patients with cirrhosis is orthotopic liver transplant.
 - 12 Spontaneous bacterial peritonitis is a potentially lethal complication of unknown etiology associated with portal hypertension with ascites that occurs in up to 10% of patients.
-

CIRRHOSIS

Background and Definition

Cirrhosis is the end result of multiple, varied, repeated, or chronic pathologic insults to the liver with subsequent repair that cause a derangement in the hepatic architecture; the primary histologic features are marked fibrosis, destruction of vascular and biliary elements, regeneration, and nodule formation (Fig. 59-1). In addition to progressive decrease of hepatic function, portal hypertension is the most prominent clinical manifestation associated with cirrhosis, but it is possible to have portal hypertension

in the absence of cirrhosis. The continuum of cirrhosis to liver cancer and its devastating clinical consequences requires us to consider hepatocellular carcinoma (HCC) as a central complication of cirrhosis. Although the only definitive cure for cirrhosis remains liver transplantation, advances in the medical management of both the inciting factors of cirrhosis as well as its complications have led to remarkable improvements to both the quantity and quality of life in patients suffering from cirrhosis.

Pathophysiology

1 Cirrhosis is caused by a wide range of pathologic entities, including the viral hepatitises, alcohol, metabolic disorders, drug toxicity, and biliary obstruction, among others (Table 59-1). Triggered by the underlying cause, the liver is exposed to a broad range of pathologic injuries leading to hepatocyte death and the gradual loss of architectural integrity made permanent by the development of fibrosis. The capacity of the liver to regenerate is a distinct feature of the liver metaphorically represented in the Promethean myth, and the liver is able to absorb injury without structural alteration. However, the capacity of the liver to regenerate is finite, and understanding the deviation from successful regeneration with restoration of hepatocyte mass and normal architecture to the path leading to fibrogenesis and cirrhosis remains a central question in liver biology.^{1,2} Significant progress in our understanding of the evolution of liver fibrosis, which ends with cirrhosis, has been gained in recent years.

The pathway from the injuring agent to fibrosis is of growing interest, and the central role of oxidative stress and chronic inflammation in many forms of liver injury has received growing attention. Oxidative stress and chronic inflammation appear to be the final common pathway in the development of cirrhosis. With ongoing inflammation, hepatocyte stress and death via apoptosis and necrosis lead to activation of hepatic stellate cells (HSCs), which appear to be the key mediator in the development of fibrosis.³ Apoptotic bodies in particular appear to play a major role in the activation of HSCs as well as Kupffer cells, the resident macrophages of the liver.⁴ Activation of these cells in turn leads to elaboration of proinflammatory and profibrogenic cytokines such as transforming growth factor beta 1 (TGF-β1) and platelet-derived growth factor (PDGF), creating a self-sustaining cycle.⁵⁻¹⁰

Figure 59-1. Evolution of cirrhosis. Fibrosis develops in nonregenerative necrotic areas, producing scars. The pattern of nodularity and scars reflects the type of response to injury (e.g., uniform vs. nonuniform necrosis) and the extent of injury.

Alcoholic liver disease has long been known to be associated with consequences of oxidative stress in the liver with failure of homeostatic mechanisms.¹¹ Obesity and metabolic syndrome, a major health problem in the United States, may produce hepatic injury and may potentiate the effects of viral injury.^{12,13} In addition to direct oxidative stress, hepatocyte injury is mediated by a variety of mechanisms including proinflammatory cytokines¹ and failure of reparative or modulatory pathways.¹⁴

The failure of protective or reparatory mechanisms is also widely studied.¹⁵ Over time, fibrosis is the

inexorable consequence of ongoing hepatic injury. HSCs are located in the perisinusoidal space of Disse (Fig. 59-2).¹⁶ In the normal liver, these cells are quiescent and are primarily responsible for the storage of vitamin A.¹⁷ Injured hepatocytes release soluble factors that activate HSCs to differentiate into myofibroblastic HSCs, as evidenced by cellular enlargement and proliferation, an increase in rough endoplasmic reticulum, loss of vitamin A droplets, expression of actin filaments, and increased expression of “fibril-forming” collagen types I, III, and V.¹⁸ They also express components of the extracellular matrix, including heparan sulfate, dermatan, chondroitin sulfate,¹⁹ laminin,²⁰ and fibronectin.²¹ Kupffer cells secrete TGF- β 1, which appears to be critical for the activation of HSCs.^{5,22} Both TGF- β and PDGF have been shown to enhance proliferation and fibrogenesis in animal models,^{5,7,23} with TGF- β being the primary stimulator of collagen synthesis and fibrosis. Further evidence implicating TGF- β in the production of hepatic fibrosis is the observation that levels of TGF- β are reduced by therapy with interferon- α in patients who are positive for hepatitis C. This reduction has been correlated with a regression of hepatic fibrosis.²⁴

CLASSIFICATION

Table 59-1 Classification of Cirrhosis

Alcohol
Viral hepatitis
Biliary obstruction
Primary
Secondary
Veno-occlusive disease
Hemochromatosis
Wilson disease
Autoimmune
Syphilis
Drugs and toxins
α_1 -Antitrypsin deficiency
Cystic fibrosis
Glycogen storage disease
Other metabolic diseases
Sarcoidosis
Copper
Small-bowel bypass
Idiopathic

In addition to the well-characterized effects of TGF- β 1 and PDGF on activating HSCs, more recent research has demonstrated the central role of Hedgehog (Hh) in activation of HSCs and promotion of fibrosis.²⁵ Hh is a molecule involved in signaling pathways that help determine cell fate during embryogenesis. The Hh ligand binds to its cell surface receptor patched. Binding of Hh to patched releases another effector, named smoothened, from a chronic state of inactivation. Activation of smoothened leads to downstream activation of a number of proteins involved in nuclear transcription, thereby leading to changes in cell fate and differentiation.²⁵ In the liver, the two primary forms of Hh are Sonic Hedgehog (SHh) and Indian Hedgehog (IHh), which are expressed by hepatocytes, bile duct cells, and HSCs. In the healthy liver, quiescent HSCs and endothelial cells keep Hh inactive by production of inhibitory proteins. When the liver is injured, however, numerous cell types including hepatocytes, cholangiocytes, HSCs, progenitor cells, lymphocytes, duct cells, and endothelial cells produce elevated levels of Hh under the influence of cytokines such as PDGF and TGF- β .^{25–30} Activation of the Hh pathway tends to be self-sustaining and resistant to negative feedback as long as the injury process continues.³¹ It is this surge in Hh levels within the local hepatic milieu that signals quiescent HSCs to activate. The critical role of Hh signaling in HSC activation and fibrogenesis was recently demonstrated by Michelotti et al.,³² who showed that deletion of the Hh intermediary smoothened was sufficient to inhibit both HSC activation and fibrosis formation.

Figure 59-2. Matrix and cellular alterations in hepatic fibrosis. **A:** In normal liver, a modest amount of low-density matrix is present in the subendothelial space of Disse. **B:** In the fibrotic liver, the accumulation of fibril-forming matrix in this region leads to “capillarization” of the sinusoid and functional changes in all neighboring cell types.

Another interesting concept that has been gaining increasing recognition is the role of the gut microflora in the development of cirrhosis. Alcoholics, for example, are known to have a greater susceptibility to small intestinal bacterial overgrowth along with alterations in their gut microflora. This bacterial overgrowth and dysbiosis lead to increased levels of LPS, which reach the liver to stimulate Kupffer cells to produce proinflammatory cytokines. The end result is the generation of mitochondrial damage, reactive oxygen species, and ongoing hepatic inflammation.^{33–35} A similar role for alterations in gut microflora has been demonstrated in nonalcoholic fatty liver disease (NAFLD).^{36,37}

As a result of the activation of stellate cells and a subsequent enhancement in collagen and extracellular matrix synthesis, the space of Disse becomes thickened, so that “capillarization” develops and the normal fenestrated architecture of the sinusoidal endothelium is lost.³⁸ Obliteration of sinusoidal fenestrations may be the essential component of fibrosis-induced hepatocellular dysfunction in cirrhosis, preventing the normal flow of nutrients to hepatocytes and increasing vascular resistance.³⁹ In addition, production of endothelin-1, a potent vasoconstrictor, by endothelial or stellate cells can cause contraction of the myofilaments within the stellate cell, influencing blood flow to injured areas and contributing to portal hypertension.⁴⁰ Initially, fibrosis may be reversible if the inciting agents are removed. With sustained injury, the process of fibrosis becomes irreversible and leads to cirrhosis. Growing attention has been given to approaches that might disconnect hepatic injury from the inexorable path of fibrosis.⁴¹

Among the most promising agents currently receiving the greatest attention in the treatment of fibrosis are the antioxidants.⁴ The combination of N-acetylcysteine and metformin taken for 12 months has demonstrated reduction of fibrosis severity in patients with nonalcoholic steatohepatitis (NASH).⁴² The glutathione donor S-adenosylmethionine (SAME) has demonstrated improved mortality in alcoholic cirrhosis, and vitamin E has been shown to improve hepatic fibrosis in the setting of NAFLD.⁴ While the results of studies utilizing these agents have had mixed results, ongoing investigations should establish their role in the treatment of fibrosis. Other studies have focused on utilization of inducible pluripotent stem cells and embryonic stem cells to replenish functional hepatocytes and restore liver function. Mesenchymal stem cells have been studied for their ability to reduce the profibrotic and proinflammatory milieu in the setting of hepatic damage. While these studies are in early stages, their potential is exciting.^{43,44}

Classification Systems

Morphology

In 1977, the World Health Organization divided cirrhosis into three categories based on the morphologic characteristics of hepatic nodules (Fig. 59-3).⁴⁵

Micronodular Pattern. Nodules are almost always less than 3 mm in diameter, are relatively uniform in size, are regularly distributed throughout the liver, and rarely contain portal tracts or efferent veins. Micronodular livers are usually of normal size or are mildly enlarged, and the fibrous septa vary in thickness. These changes reflect relatively early disease and are characteristic of a wide range of disease processes, including alcoholism, biliary obstruction, venous outflow obstruction, hemochromatosis, and Indian childhood cirrhosis.

Macronodular Pattern. In this category, nodules vary considerably in size and are larger than 3 mm in diameter, with some nodules measuring several centimeters. Portal structures and efferent veins are present but display architectural distortion. These livers are usually coarsely scarred with variably thick and thin septa and may be either normal or reduced in size. Two separate subcategories are recognized based on the nature of the fibrous septa. In the first category, characteristic of “posthepatitis” pathology and found in Wilson disease, fine, sometimes incomplete septa link portal tracts; these are difficult to see on gross inspection of the liver. The second is characteristic of “postnecrotic” disease, commonly found in patients with viral hepatitis, and is characterized by coarse, thick septa that are readily apparent on gross examination. Because of the relatively large size of the nodules relative to the size of biopsy specimens, diagnosis by biopsy may be difficult in macronodular cirrhosis.

Figure 59-3. A: Small, shrunken liver and a fairly regular pattern of nodularity. This appearance is rather typical of end-stage cirrhosis, regardless of the cause. B: Photomicrograph of cirrhotic liver tissue, showing irregular nodules of regenerating hepatocytes surrounded by scar. Trichrome stain. (From Stal P, Broome U, Scheynius A, et al. Kupffer cell iron overload induces intercellular adhesion molecule-1 expression on hepatocytes in genetic hemochromatosis. *Hepatology* 1995;21:1308–1316.)

Mixed Pattern. This description is applied to livers in which both micronodules and macronodules are present in approximately equal proportions.

Etiology

Another commonly used method for classifying cirrhosis is by etiology. The causes of cirrhosis and the morphologic and histologic characteristics of the liver, however, overlap significantly. Oxidative stress leading to chronic injury and inflammation appears to be a common theme of these disorders, which leads to both scar formation and an increased risk of liver cancer.

Alcohol. The relationship between alcohol and liver disease has been well established. In 1849, Rokitansky, referring to the association of alcohol intake and liver disease, coined the term *Laennec cirrhosis*.⁴⁶ Consumption of at least 30 g of alcohol per day in women and 50 g of alcohol per day in men over at least 5 years is considered to be the minimum threshold alcohol intake for cirrhosis to develop.⁴⁷ More than 50% of alcoholics with cirrhosis and two-thirds of patients with alcoholic hepatitis and cirrhosis die within 4 years of diagnosis.⁴⁸ Alcoholic cirrhosis is the second leading indication for liver transplantation overall, accounting for 40% of liver transplants in Europe and 25% in the United States.^{49–51} Cirrhosis, however, develops in only 10% to 30% of heavy drinkers.⁵² The reasons why cirrhosis develops in some alcoholics but not in others are not clear and may depend on a variety of factors, such as genetic predisposition, nutritional effects, concomitant drug use, and viral infection.

Alcoholic liver disease usually begins with a transition of normal architecture to fatty liver and

alcoholic hepatitis, indicated histologically by the presence of megamitochondria, Mallory bodies (eosinophilic accumulations of intermediate filaments with cytokeratin proteins), inflammation and necrosis, and ultimately fibrosis (Fig. 59-4). Classically, the morphology of alcoholic cirrhosis is a micronodular pattern.

2 Although alcohol may directly activate stellate cells to produce collagen independently of inflammation and necrosis,⁵³ the key mediator in alcohol-induced liver disease is acetaldehyde, the product of alcohol metabolism by the enzyme alcohol dehydrogenase. Acetaldehyde (ADH) produces numerous deleterious effects on the liver, including the following: direct activation of stellate cells⁵⁴; inhibition of DNA repair⁵⁵; depletion of glutathione, which impairs mitochondrial function and the ability to handle free radical production; damage to microtubules, which causes protein and water sequestration⁵²; and formation of reduced nicotinamide adenine dinucleotide (NADH), which opposes gluconeogenesis and inhibits fatty acid oxidation, so that steatosis and hyperlipidemia develop.⁵² ADH is most active in the perivenular/centrilobular zone 3 of the hepatic lobule; as a result, relatively high concentrations of acetaldehyde are found in this area of the liver. In addition, zone 3 is hypoxic because of its distance from portal venous and hepatic arterial inflow. These two factors are presumably responsible for the characteristic initial perivenular location of alcohol-induced liver disease.

Figure 59-4. Alcoholic hepatitis. Mallory bodies (arrows) are evident within the swollen, clear cytoplasm of several hepatocytes. This hyaline material is chemotactic for leukocytes, many of which are seen within the field. Hematoxylin and eosin (H&E) stain $\times 470$.

Other effects of ADH include induction of lipid peroxidation with subsequent loss of integrity of cell membranes, which causes the characteristic “ballooning degeneration” of alcohol-induced liver disease. In addition to its direct hepatic effects, ADH is now known to play a major role in the derangement of the gut–liver axis which plays a key role in alcohol-induced liver injury.⁵⁶ In the “leaky gut hypothesis,” ADH increases the permeability of the intestinal barrier,⁵⁷ allowing bacterial endotoxin (LPS) access to the liver via the portal circulation. Excess circulating endotoxin then activates Kupffer cells through interaction with Toll-like Receptor 4 (TLR4) to set off the inflammatory cascade responsible for the development of alcoholic liver disease.³⁵ Necrosis and inflammation in the perivenular region activate the stellate cells in the space of Disse, so that fibrosis develops. With continued ingestion of alcohol and hepatic injury, expansion of the areas of fibrosis toward the periportal regions leads to bridging fibrosis and ultimately cirrhosis.

3 Nonalcoholic Fatty Liver Disease/Nonalcoholic Steatohepatitis. As noted earlier, this entity has become a major health problem in the United States and adds even further to the litany of health consequences of obesity. NASH, as this disease was previously called, is only one stage in the NAFLD process.⁵⁸ NAFLD is now the most common cause of chronic liver disease in the United States, affecting up to 30% to 46% of the population.^{59,60} NASH-related cirrhosis is expected to surpass viral hepatitis as the leading indication for liver transplantation by 2025.²⁵ It is characterized by infiltration of the liver with fat, with or without inflammation (hepatitis), which shares pathologic features of alcohol-induced liver injury but occurs in patients who do not abuse alcohol. NAFLD is associated with obesity, hyperlipidemia, cardiovascular disease, and noninsulin-dependent diabetes, with 90% of NAFLD patients having at least one of these risk factors and 30% having three or more.⁶¹ It now appears that most patients traditionally diagnosed with cryptogenic cirrhosis have NAFLD.⁶² In addition to liver injury and cirrhosis, NAFLD is a major risk factor for primary liver cancer HCC and, in addition to hepatitis virus infection, accounts for the rapid rise in the incidence of HCC in Western countries.⁶³ More broadly

considered, recent reports have identified obesity as a major risk factor for cancer deaths with a 4.5-fold increase of the relative risk for liver cancer in obese subjects.⁶⁴

The current understanding of NAFLD and progression to NASH and cirrhosis involves a two-hit model, which is nicely explained in a review by Bohinc and Diehl.²⁵ In this model, insulin resistance leads to hepatic steatosis (the first hit), which sensitizes the hepatic parenchyma to environmental and extracellular insults (the second hit) leading to inflammation, necrosis, and fibrosis.²⁵ Dietary fructose has been identified as an important culprit in the development of hepatic steatosis by decreasing intracellular ATP and transforming to lipid in the absence of insulin.⁶⁵ Ongoing hepatic insults lead to activation of the inflammasome, a protein scaffold that results in the secretion of the inflammatory cytokines IL-1 β and IL-18, further amplifying hepatic inflammation and injury. Inflammasome activation is increased by gut-derived bacterial endotoxin. This inflammation promotes increased Hh signaling and stellate cell activation with resultant fibrosis.⁶⁶

Therapy for NASH centers on lifestyle modification, with a modest weight loss of 5% to 10% associated with significant histologic improvements in disease severity.⁶¹ Now that the role of gut microflora is understood to play a major role in the pathogenesis of NASH and other liver diseases, the use of probiotics, most commonly lactobacilli and bifidobacteria, is being explored in the treatment of NASH. A recent meta-analysis of four randomized controlled trials demonstrated probiotics significantly decreased transaminases, total cholesterol, TNF- α , and insulin resistance.⁶⁷

4 Hepatitis. Viral hepatitis is the most common cause of cirrhosis worldwide, accounting for at least 50% of cases. Hepatitis A, B, C, D, and E have all been proved to cause acute hepatitis, characterized histologically by lymphocytic parenchymal and portal inflammations, focal necrosis, ballooning degeneration, cholestasis, Kupffer cell and macrophage hypertrophy and hyperplasia, and lobular disarray. Only hepatitis B, C, and D have been shown to progress to chronic hepatitis, defined by persistent liver cell necrosis and inflammation lasting longer than 6 months. Chronic infection with hepatitis B virus (HBV) develops in fewer than 5% of patients who experience acute HBV infection. The development of cirrhosis in approximately 10% to 20% of chronically infected persons produces an overall rate of cirrhosis of approximately 1%. Hepatitis B remains a major public health problem in Asian countries and Africa, with up to 10% of the population showing evidence of chronic infection. The widespread use of antiviral medications effective against hepatitis B effectively suppresses viral replication to undetectable levels in up to 90% of patients, and may reverse fibrosis and even cirrhosis. Even with effective suppression of viral replication, however, HBV is not truly “cured” since the virus is incorporated into the host genome. This has important consequences as HCC can still develop in the noncirrhotic liver of HBV-infected patients.⁶⁸ In addition, public health strategies with systematic vaccination of newborns should substantially decrease the incidence of new infections.

In contrast, hepatitis C poses a much higher risk of chronic infection, and therapeutic strategies eradicate viral replication in a minority of patients. Of patients with hepatitis C virus (HCV), 90% become chronically infected, and chronic hepatitis develops in 60% of these patients. Among patients with chronic hepatitis, 30% progress to cirrhosis,⁴⁶ so that the incidence of cirrhosis in patients initially infected with hepatitis C is approximately 10%. Standard treatment for HCV was previously based on the combination of pegylated interferon and ribavirin, with sustained viral response (SVR) rates of up to 80% in patients with genotypes 2 and 3,⁶⁹ but results for the more common genotype 1 were only 40% to 50%, with the best reporting an SVR rate of 65%.⁷⁰ Compounding the limited efficacy of interferon-based therapy is the high rate of adverse events that prevents many patients from completing therapy.

The recent release of a new wave of oral antiviral therapies, termed direct-acting antivirals (DAAs), and allowing interferon-free regimens, however, has demonstrated more promising results (Table 59-2).

The fixed dose combination of 90-mg ledipasvir and 400-mg sofosbuvir is sold under the trade name Harvoni (Gilead Sciences) and is recommended as first-line therapy by the American Society for the Study of Liver Disease (AASLD) for the treatment of HCV genotypes 1a, 1b, and 4.⁷¹ Ledipasvir is an inhibitor of the HCV protein NS5A, which limits viral replication. Sofosbuvir is a nucleotide inhibitor of the NS5B polymerase that terminates viral replication. In the ION-1 trial that leads to approval of the combination of these two agents for the treatment of HCV genotype 1, SVR rates of 97% to 99% were demonstrated after 12 weeks of therapy. No patients who received the 12-week regimen had adverse effects leading to early treatment discontinuation.⁷² For treatment of genotype 4, the SYNERGY trial demonstrated an SVR rate of 95% by intention to treat analysis following 12 weeks of ledipasvir/sofosbuvir therapy.⁷¹ Ledipasvir/sofosbuvir is also recommended as first-line therapy for genotype 6. Sofosbuvir also has significant activity against genotypes 2 and 3 when combined with ribavirin, and genotypes 5 and 6 when combined with ribavirin and pegylated interferon.⁷¹ Simeprevir

is a novel NS3/4A protease inhibitor recommended as first-line therapy for HCV for genotypes 1a and 1b when used in combination with sofosbuvir. In the COSMOS trial, combination simeprevir/sofosbuvir for genotype 1 HCV demonstrated 95% SVR after 12 weeks of therapy in noncirrhotics, and 100% SVR after 24 weeks of therapy in cirrhotics.⁷³

ETIOLOGY

Table 59-2 Causes of Cholestasis

Extrahepatic	Vanishing bile duct syndrome
Common bile duct stones	Allograft rejection
Cancers	Graft versus host disease
Pancreas	Alagille syndrome
Ampulla of Vater	Idiopathic adult ductopenia
Bile duct	Primary sclerosing cholangitis
Cysts	Hodgkin disease
Pancreatic	Cystic fibrosis
Choledochal	
Infections	Hepatocellular Cholestasis
Parasites	Genetic
Acquired immunodeficiency syndrome	α -Antitrypsin deficiency
Chronic pancreatitis	Benign recurrent intrahepatic cholestasis
Bile duct strictures	Byler syndrome
Benign	Cholestasis of pregnancy
Ischemic	Abnormal bile acid synthesis
Hodgkin disease	Porphyrias
Biliary atresia	Acquired
Intrahepatic	Viral hepatitis
Primary biliary cirrhosis	Drugs
Space-occupying lesions	Alcoholic hepatitis
Primary or metastatic hepatic tumors	Bacterial infections
Lymphoma	Total parenteral nutrition
Amyloidosis	Renal carcinoma
	Hodgkin disease
	Postoperative cholestasis

Another novel all-oral HCV regimen is the combination of ombitasvir, paritaprevir, ritonavir, and dasabuvir, marketed as the Viekira Pak (AbbVie). Ombitasvir inhibits NS5A, paritaprevir inhibits the NS3/4A protease, ritonavir is a CYP3A4 inhibitor without any HCV activity used to increase sensitivity to paritaprevir, and dasabuvir is a nonnucleotide NS5B polymerase inhibitor. The combination is recommended as first-line therapy for genotype 1a when used with weight-based ribavirin, genotype 1b (with ribavirin for cirrhotics), and genotype 4 (with ribavirin).⁷¹ Against HCV genotype 1, SVR rates of 95.3% to 97% have been demonstrated.^{74,75}

These results represent a revolution in the therapy of HCV that makes cure of HCV a possibility. In patients who respond to therapy, progression to cirrhosis is eliminated and it is generally thought that HCC does not develop. In patients who do not respond to therapy, cirrhosis develops in approximately 40%, and HCC develops in 16% of these patients.⁷³

Hepatitis D virus (HDV) is an RNA virus that requires the presence of HBV to be pathogenic. Superinfection of HBV-positive patients with HDV leads to a more rapid clinical course, with progression to cirrhosis in 70% to 80% of patients.⁷⁴ Among patients with compensated cirrhosis of viral origin, HCC developed in approximately 20% with HCV, 9% with HBV, and 41% with both HBV and HCV.⁴⁶ The progressive increase in hepatitis-infected individuals in the United States precedes an epidemic in HCC, which has been well documented and is expected to peak over the coming decade.⁷⁵

Cholestasis. Cholestasis, defined as a decrease or absence of bile flow into the duodenum, may be caused by intrahepatic or extrahepatic biliary obstruction or defects in the ability of hepatocytes to excrete bile. Causes of cholestasis are presented in Table 59-2. Prolonged biliary obstruction leads to proliferation of bile ducts, formation of bile lakes caused by disruption of bile ducts, fibrosis, and ultimately secondary biliary cirrhosis as a result of the direct toxic effects of bile salts on hepatobiliary elements.

Immune or Inflammatory Cirrhosis. Although cholestasis is a generically toxic insult to the liver that can cause cirrhosis, several diseases that are characterized by cholestasis seem to be caused by underlying immune or inflammatory disorders affecting either small (primary biliary cirrhosis [PBC]) or large (primary sclerosing cholangitis [PSC]) bile ducts. PBC is a chronic, slowly progressive disease that

most commonly affects middle-aged women; it is characterized by portal inflammation, destruction of intrahepatic bile ducts, and progression to cirrhosis. Approximately 95% of patients are women, and 95% of these women express antimitochondrial antibodies in serum.⁷⁶ The autoimmune inflammatory process damages both the bile ducts and, eventually, the hepatocytes as a result of leakage of bile acids into surrounding parenchyma.⁷⁷ Patients present with fatigue, jaundice, and pruritus, but as many as 60% of patients may be asymptomatic.⁷⁸ PBC progresses in the majority of patients; median survival times are approximately 10 to 15 years in asymptomatic patients and 7 years in symptomatic patients.^{79,80} Poor prognostic factors include hyperbilirubinemia, advanced age, hepatosplenomegaly, and symptomatic disease.

Medical management of PBC is with the exogenous bile acid ursodeoxycholic acid (13 to 15 mg/kg/d). Complete response, as evidenced by normalization of liver enzymes without histologic progression, is seen in up to 30% of patients and can even lead to a normal life expectancy. Therapy for nonresponders includes immunosuppression with methotrexate, colchicine, or steroids, although the efficacy of these medications is in question.⁸¹ Liver transplantation is ultimately required as the definitive treatment in most patients, and the parameters for liver transplantation and its timing are relatively predictable and have been well studied.⁸²

PSC is a chronic, progressive cholestatic liver disease of unknown cause characterized by diffuse segmental intrahepatic or extrahepatic biliary ductular strictures with associated fibrosis and inflammation. The disease has no cure and often leads to secondary biliary cirrhosis, portal hypertension, hepatic failure, and cholangiocarcinoma if hepatic transplantation is not performed. PSC is strongly associated with inflammatory bowel diseases, most commonly ulcerative colitis, and probably shares an underlying disturbance related to disturbed mucosal immunity of the gastrointestinal tract.⁸³ Approximately 70% of patients with PSC also have ulcerative colitis.⁸³ Conversely, approximately 5% of patients with ulcerative colitis have PSC, though subtler forms of the disease may be present but clinically asymptomatic. PSC is thought to be autoimmune in nature; elevated levels of autoantibodies and an increased expression of human leukocyte antigen (HLA) class II molecules on biliary epithelial cells have been observed.^{84,85} Approximately two-thirds of patients are male and younger than 45 years of age at the time of diagnosis.⁸⁶ Patients with PSC may be completely asymptomatic (up to 44%) or have signs of advanced disease at the time of diagnosis.⁸³ Commonly, the diagnosis is made in symptomatic patients after endoscopic retrograde cholangiopancreatography (ERCP) has been performed to evaluate elevated liver enzymes, including alkaline phosphatase and γ -glutamyltransferase. Symptomatic patients have a waxing and waning course and may present with complaints of fatigue (75%), pruritus (25% to 70%), jaundice (30% to 69%), abdominal pain (16% to 37%), and weight loss (10% to 34%).⁸³ Complications secondary to progression to cirrhosis are less common and include ascites, variceal bleeding, and acute cholangitis.

The diagnosis of PSC is suggested by a history of inflammatory bowel disease in the setting of elevated liver enzymes and is established by cholangiography. The disease process may range from a single dominant stricture to, more commonly, diffuse multifocal sclerosis of the intrahepatic and extrahepatic bile ducts. Pathologically, bile ductular proliferation, periductal fibrosis and inflammation, ductopenia, and, less commonly, obliterative fibrous cholangitis may be present. PSC may be considered a premalignant condition. Like ulcerative colitis, PSC confers a significant risk of malignant transformation of the biliary mucosa, which is one of the considerations in considering patients for transplantation.⁸⁷ Cholangiocarcinoma develops in 1% to 2% of patients per year after the diagnosis of PSC, with an overall risk of up to 10%.⁸⁸ Screening for premalignant changes with ERCP and cytologic examination and serum testing of CA19-9 have been helpful, though both have limited specificity and sensitivity. Recently, it has been proposed that newer analysis methods of biliary material obtained at screening ERCP, including fluorescence in situ hybridization (FISH), may be used for chromosomal abnormalities associated with cancer with an increase in the sensitivity.⁸⁹

There is no generally accepted medical therapy to treat PSC, so therapeutic efforts are directed toward complications of the disease. The major complications include biliary obstruction, cirrhosis, and cholangiocarcinoma. Dominant strictures, defined as stenosis less than 1.5 mm in the common bile duct or less than 1 mm in the hepatic duct, are readily treated endoscopically by means of dilation and/or stent placement.^{90,91} Transplantation should be performed before cancer develops and, generally, the discovery of cancer has been considered an absolute contraindication to transplantation because of poor outcomes. Highly selected patients with localized tumors may be transplanted with an acceptable survival rate with intensive preoperative therapy including radiation and chemotherapy, as proposed by Shaw and implemented on a larger scale by the Mayo group.⁹²

Metabolic and Genetic Disorders. Some of these diseases are listed in [Table 59-1](#). A description of all the metabolic disorders causing liver disease is beyond the scope of this chapter.

In hemochromatosis of the liver, an inborn error of metabolism causes an increased absorption of iron from the gastrointestinal tract. The pathophysiology of iron-induced hepatotoxicity is related to lipid peroxidation induced by iron in periportal regions of the liver. Activation of stellate cells by cytokines released from Kupffer cells that have phagocytosed necrotic hepatocytes injured by iron toxicity is also contributory.⁹³ Over time, the reaction progresses to bridging fibrosis and eventually to a mixed micronodular–macronodular cirrhosis. Treatment includes reduction of iron intake, repeated phlebotomy, and orthotopic liver transplantation.⁹⁴

Wilson disease is an autosomal, recessively inherited disease caused by a deficiency in hepatocyte transport of copper into the bile. The disease is characterized biochemically by low serum ceruloplasmin levels and clinically by corneal pigmentation (Kayser–Fleischer rings), neuropsychiatric disease, and hepatic cirrhosis.⁹⁵ As copper accumulates in the liver, periportal inflammation develops that leads to piecemeal and lobular necroses, bridging fibrosis, and a mixed micronodular–macronodular cirrhosis. Treatment options include chelating agents, such as penicillamine, trientine, zinc salts, and orthotopic liver transplantation.

Venous Outflow Obstruction. Cirrhosis may also result from obstruction of the hepatic veins. Causes include chronic right-sided heart failure as a result of severe tricuspid regurgitation, constrictive pericarditis, and the Budd–Chiari syndrome (BCS).

Hepatic dysfunction secondary to passive vascular congestion in the setting of right-sided heart failure and increased right-sided heart pressures is caused by the transmission of increased pressure to the hepatic venous system. This increased pressure leads to sinusoidal congestion, perivenular atrophy, hemorrhagic necrosis, and distortion and enlargement of sinusoidal fenestrations.⁹⁶ Increased pressure also causes perisinusoidal edema that eventually exceeds the clearance capabilities of hepatic lymphatics, so that ascites develops.⁹⁷ Grossly, the liver is described as having a “nutmeg” appearance in which areas of hemorrhage are interspersed with relatively normal yellowish parenchyma.⁹⁷ Histologically, perivenular fibrosis progresses to bridging fibrosis that spares the portal regions. Portal sparing is characteristic of “cardiac cirrhosis.” In addition to causing ascites, chronic vascular congestion can lead to fibrosis in the space of Disse, which compromises nutrient delivery and contributes to portal hypertension and zone 3 hepatocellular injury.⁹⁸

5 BCS is a rare disease caused by mechanical obstruction of the hepatic veins ([Table 59-3](#)). Obstruction may occur at the level of the terminal hepatic veins, the major hepatic veins, or the vena cava and may be caused by obstructing webs or membranes (most commonly in Africa and Asia) or thrombosis secondary to hypercoagulable states and neoplasms (most commonly in the West).

The range of presentations is wide; some patients are completely asymptomatic, whereas acute hepatic failure or cirrhosis develops in others.⁹⁹ These variations in symptoms are related to the degree and rate of progression of hepatic outflow obstruction. Patients classically present with abdominal pain, hepatomegaly, and ascites. The diagnosis can be made by duplex Doppler ultrasonography, which has a sensitivity of 85% to 95%.¹⁰⁰ Identification of collateral vessels to subscapular or intercostal vessels on ultrasonography on ultrasound is a highly sensitive and specific finding.¹⁰¹ Computed tomography (CT) and magnetic resonance imaging (MRI) offer optimal characterization of intrahepatic vascular anatomy and are currently used for the planning of complex interventions.¹⁰² Medical management consists of anticoagulation and symptomatic management. Interventional radiologic procedures have now taken the forefront in management of BCS, in which accessible strictures may be treated with angioplasty or stenting. For patients unsuitable for reestablishment of hepatic venous outflow through the above means, transjugular intrahepatic portosystemic shunting (TIPS) is able to decompress both the inferior vena cava and the portal system.¹⁰¹ In patients with fulminant BCS or in those who develop chronic decompensated cirrhosis, liver transplantation becomes an option.

ETIOLOGY

Table 59-3 Etiology

Idiopathic
Hematologic disorders
Polycythemia vera
Paroxysmal nocturnal hemoglobinuria
Myeloproliferative disorders
Antithrombin III deficiency
Circulating lupus anticoagulants
Oral contraceptives
Pregnancy and postpartum

Adrenal carcinoma
Leiomyosarcoma of the inferior vena cava
Vena caval webs
Infections
Amebic abscess
Aspergillosis
Hydatid cyst
Phlebitis
Trauma
Veno-occlusive disease

Diagnosis

Although cirrhosis can be asymptomatic for decades, significant information can be obtained by performing a thorough history and physical examination. A history of alcohol abuse, hepatitis, toxin or drug exposure, upper gastrointestinal bleeding, enlarging hemorrhoids, infections, and alteration in mental status suggests the possibility of liver disease. Physical findings associated with cirrhosis are listed in [Table 59-4](#). In addition to these findings, fetor hepaticus, purpura and bruising, decreased body hair, and white nails are common.

Laboratory tests of liver function are indicated if liver disease is suggested by the history and physical examination. Although levels of bilirubin, aspartate aminotransferase, alanine aminotransferase, and alkaline phosphatase are elevated in hepatic disease, the increases are not specific for liver pathology, and levels may be normal even in the setting of significant disease. A very common finding in patients with cirrhosis is thrombocytopenia, caused by hypersplenism and portal hypertension. The platelet growth factor thrombopoietin, which is produced by the liver, has been shown to be decreased in patients with cirrhosis, and this deficit may contribute to the thrombocytopenia associated with hepatic disease.¹⁰³

The definitive diagnosis of cirrhosis usually requires biopsy, either percutaneous or operative, or gross inspection during laparoscopy or laparotomy. Regardless of the method selected, it is crucial to obtain a large enough specimen to make the diagnosis. Current recommendations suggest that at least 11 portal tracts need to be assessed.¹⁰⁴ Several staging systems exist for the grading of fibrosis and cirrhosis, including the International Association for Study of the Liver (IASL), Batts–Ludwig, and Metavir systems. The AASLD recommends the Batts–Ludwig system as it gives a verbal diagnosis rather than numeric categories, and thus may be easier to interpret.¹⁰⁴

DIAGNOSIS

Table 59-4 Physical Findings in Cirrhosis

Physical Findings	Incidence (%)
Palpable liver	96
Jaundice	68
Ascites	66
Spider angiomas	49
Dilated abdominal wall veins	47
Palpable spleen	46
Testicular atrophy	45
Palmar erythema	24
Noninfectious fever	22
Hepatic coma	18
Gynecomastia	15
Dupuytren contractures	5

Noninvasive methods to diagnose cirrhosis include ultrasonography, CT, and MRI, which generally reveal an atrophic, nodular liver and an enlarged spleen. More recent work suggests that subtle changes in the hepatic veins may be early markers of cirrhosis.¹⁰² Ultrasonographic criteria for cirrhosis include the demonstration of multiple nodular irregularities on the ventral liver surface that are clearly separate from the anterior abdominal wall. Parenchymal texture is altered in the setting of fibrosis, though this feature can be subtle. When these criteria are used, ultrasonography has been shown to have a sensitivity, specificity, and accuracy of approximately 90% in the diagnosis of cirrhosis.¹⁰⁵ Ultrasound-based transient elastography, a measure of liver stiffness, is playing an increasingly large role in the noninvasive assessment of fibrosis, with some studies demonstrating a 95% area under the receiver operating characteristic curve (AUROC) for diagnosing grade IV fibrosis (cirrhosis).¹⁰⁶

More recently, several laboratory indexes have been found to correlate well with histologic grade of cirrhosis.^{106,107} The NAFLD fibrosis score, for example, consists of age, BMI, diabetes, platelet count, albumin level, and AST/ALT ratio.¹⁰⁸ The AUROC of this scoring system in diagnosing stage 3 or greater fibrosis was 85% in a recent meta-analysis.¹⁰⁹ The Fibrotest (LabCorp) is a patented panel of biomarkers consisting of GGT, haptoglobin, bilirubin, apolipoprotein A1, and alpha-2-macroglobulin. The AUROC of Fibrotest for fibrosis greater than or equal to stage 2 has been shown to be up to 87%.¹¹⁰ Indirect evidence of cirrhosis includes endoscopically discovered varices of the esophagus, and the presence of splenomegaly detected by CT or MRI.

Complications

Renal

Renal complications in cirrhosis are intrinsic to functional dysregulation of vascular tone throughout the body.¹¹¹ Several elements come into play and renal dysfunction is characterized by avid sodium retention despite normovolemia or hypervolemia, dilutional hyponatremia secondary to free water overload, ascites, and ultimately renal failure and the hepatorenal syndrome (HRS). The paradoxical arterial vasoconstriction of the renal arterial bed in the face of global fluid overload is critical to the pathophysiology of HRS.¹¹² Among the complications of cirrhosis, HRS confers the highest risk of mortality.¹¹³ Although HRS is the most dramatic renal complication of liver failure, renal dysfunction in patients with advanced liver disease is generally multifactorial.¹¹² Renal insufficiency may develop in a patient with cirrhosis as a direct consequence of the underlying condition (i.e., PBC, amyloidosis), as a consequence of excessive diuretic use in the treatment of ascites and fluid overload, or as a secondary reaction to the release of cytokines or hormones by the liver that alter renal function.

DIAGNOSIS

Table 59-5 Differential Diagnosis of Acute Azotemia in Patients with Liver Disease

	Prerenal Azotemia	Hepatorenal Syndrome	Acute Renal Failure
Urinary sodium	<10 mEq/L	<10 mEq/L	>30 mEq/L
Urine/plasma creatinine ratio	>30:1	>30:1	<20:1
Urine osmolality	100 mOsm, or more than plasma osmolality	100 mOsm, or more than plasma osmolality	Equal to plasma osmolality
Urine sediment	Normal	Normal	Casts: cellular debris

Much progress has been made in the understanding of the pathophysiology of HRS focusing on the dysregulation of arterial tone in the end stages of liver disease. Empiric observations that support a functional or “secondary effect” theory include the lack of anatomic renal abnormalities in patients with cirrhosis-related renal dysfunction, the normal function of previously dysfunctional kidneys transplanted into otherwise healthy recipients, and resolution of renal abnormalities after successful hepatic transplantation. Recent clinical studies have defined the critical role of optimizing colloid balance in the patient with cirrhosis¹¹⁴ and the exploration of regulators of renal blood flow such as terlipressin in counteracting the deranged vascular tone.¹¹⁵

Sodium Retention. Patients with cirrhosis who do not have ascites have relatively normal sodium-handling capabilities. Patients in whom ascites develops have a marked inability to excrete sodium. Because of this deficit, sodium intake in excess of renal excretion contributes to fluid overload. Three

potential mechanisms have been invoked to explain the cause of sodium retention and the development of ascites in cirrhotic patients. The first is the “underfill” theory, whereby portal hypertension causes an increase in pressure in the splanchnic circulation. Ascites occurs when hepatic lymph production exceeds lymphatic return, with subsequent contraction of the blood volume and renal sodium retention.¹¹⁶ This theory was abandoned when it was shown that patients with cirrhosis were found to have increased, rather than decreased, plasma volume.¹¹⁷ The second is the “overflow” theory, which suggests that the primary defect is inherent to the kidney. Abnormal renal retention of sodium leads to concomitant water retention, expansion of plasma volume, and subsequently edema and ascites.^{117,118} The third and most currently accepted explanation is the “arterial vasodilation hypothesis,” which suggests that the responsible defect lies within the vascular system, with arterial hypotension as the primary event. Arterial vasodilation in the splanchnic circulation leads to relative peripheral hypovolemia and activation of the renin–angiotensin–aldosterone and sympathetic nervous systems. The effects, in turn, are a release of antidiuretic hormone (arginine vasopressin), enhancement of sodium and water conservation, an increase in effective circulating volume, and edema and ascites.^{119,120}

The cause of the splanchnic vasodilation is unclear. Some evidence suggests that nitric oxide may be the key mediator. Elevations in portal venous nitric oxide have been reported in both animal and human studies,^{121,122} and inhibitors of nitric oxide production have been shown to reduce the activity of vasoconstrictor systems and enhance renal hemodynamics.¹²² The exact role of nitric oxide activity in the pathophysiology of renal disease in cirrhosis remains to be determined. Other studies have demonstrated that extracellular fluid volume expansion precedes vasodilation,¹²³ and that pathologic activation of intrahepatic vascular sensors is the key mediator for the ensuing renal salt retention.¹¹⁶

Water Retention. Patients with cirrhosis and ascites may have a marked inability to handle free water. An increased production of antidiuretic hormone, decreased delivery of fluid to the diluting segments of the nephron, and reduced renal production of prostaglandins all may contribute.¹¹⁷ Retention of water leads to dilutional hyponatremia (serum sodium 130 mEq/L), which can cause nausea, vomiting, lethargy, and seizures.¹²⁴

6 Hepatorenal Syndrome. HRS is a complication of cirrhosis, most often with ascites, characterized by progressive renal failure in the absence of intrinsic renal disease. Renal dysfunction is thought to occur in up to 20% of patients hospitalized with cirrhosis and ascites.¹²⁵ In a large study of two major Spanish centers, HRS developed in 7.6% of patients admitted for the management of ascites.¹²⁶ Manifestations of the disease include progressive oliguria, with urine outputs of 400 to 800 mL/d, a rising serum creatinine level, increased cardiac output, and decreased arterial pressure. The disease process is highly variable and is associated with marked renal cortical vasoconstriction induced by activity of the renin–angiotensin–aldosterone and sympathetic nervous systems. In addition, the powerful endothelium-derived vasoconstrictor endothelin-1, combined with decreased renal production of vasodilator prostaglandins, may play a role.

HRS may develop as a result of infection, use of nonsteroidal anti-inflammatory drugs, variceal hemorrhage, or excessive diuretic use in patients who were previously well compensated. The differentiation of HRS from acute renal failure is possible by the laboratory evaluation of urine and serum samples. HRS, however, is virtually indistinguishable by laboratory testing from prerenal azotemia. Both prerenal azotemia and HRS are characterized by extremely low sodium concentrations in the urine, high urine osmolality, high urine-to-plasma ratios of creatinine, and normal urinary sediment (Table 59-5). Criteria for the diagnosis of HRS are listed in Table 59-6.

DIAGNOSIS

Table 59-6 Diagnostic Criteria for Hepatorenal Syndrome^a

Major Criteria
1. Low glomerular filtration rate, as indicated by serum creatinine >1.5 mg/dL or 24-hour creatinine clearance 40 mL/min
2. Absence of shock, ongoing bacterial infection, fluid losses, and current treatment with nephrotoxic drugs
3. No sustained improvement in renal function (decrease in serum creatinine to ≤1.5 mg/dL or increase in creatinine clearance to 340 mL/min) following diuretic withdrawal and expansion of plasma volume with 1.5 L of a plasma expander
4. Proteinuria <500 mg/d and no ultrasonographic evidence of obstructive uropathy or parenchymal renal disease
Additional Criteria
1. Urine volume <500 mL/d
2. Urine sodium <10 mEq/L
3. Urine osmolality greater than plasma osmolality
4. Urine red blood cells <50 per high-power field
5. Serum sodium concentration <130 mEq/L

^aAll major criteria must be present for the diagnosis of hepatorenal syndrome. Additional criteria are not necessary for the diagnosis but provide supportive evidence.
From Arroyo V, Ginés P, Gerbes A, et al. Definition and diagnostic criteria of refractory ascites and hepatorenal syndrome in cirrhosis. *Hepatology* 1996;23:164.

The treatment of ascites in patients with cirrhosis requires sodium and water restriction in addition to the use of diuretics. Excessive use of these treatment modalities may lead to increases in serum creatinine that can be difficult to distinguish from those of HRS. A failure to respond to cessation of diuretics and fluid challenge suggests HRS. If liver transplantation cannot be performed, patients with HRS usually die within months of the development of severe disease, defined as a serum creatinine level above 2 mg/dL.¹¹³

Management of HRS hinges on a three-pronged approach. First is treatment of the triggering event. The most common inciting factor is spontaneous bacterial peritonitis, followed by volume contraction (from multiple etiologies including gastrointestinal bleeding or the overzealous treatment of ascites). Over 70% of cases of acute HRS have been linked to bacterial infections.¹²⁷ The other two cornerstones of HRS treatment are vasoconstrictors and volume expansion with albumin. The vasopressin-analog terlipressin is commonly used outside the United States. The oral vasopressor midodrine is commonly used in the United States, where terlipressin is not approved by the FDA. Others have examined norepinephrine as a substitute for terlipressin.¹²⁷ A meta-analysis of all randomized controlled trials of vasopressor use in the treatment of HRS has found a reduction in all-cause mortality when vasopressors are utilized.¹²⁸ Although advances in medical therapy have made the reversal of HRS possible in some patients, many will ultimately require liver transplantation in order to survive.

Pulmonary

Many pathologic processes in patients with cirrhosis affect pulmonary function. Some reflect an underlying condition that causes both hepatic and pulmonary diseases (i.e., cystic fibrosis, α_1 -antitrypsin deficiency); others are primary pulmonary processes, such as interstitial lung disease, primary pulmonary hypertension (portopulmonary hypertension [POPH]), and obstructive airway disease. Three main pulmonary manifestations of cirrhosis are discussed here; one is related to increased intra-abdominal pressure secondary to ascites, one is caused by intrapulmonary shunting and is known as the hepatopulmonary syndrome (HPS), and the last is POPH.

The presence of copious ascitic fluid can lead to pulmonary dysfunction by compromising diaphragmatic excursion secondary to increases in intra-abdominal and intrapleural pressures. Ascites may also induce large pleural effusions known as hepatic hydrothorax because of the presence of lymphatic transdiaphragmatic communications between the abdomen and thorax.¹²⁹ These small diaphragmatic defects are typically found on the right side of the body. Effusions can compress the pulmonary parenchyma and impair gas exchange, so that ventilation-perfusion mismatch and hypoxemia develop. Patients present with worsening pulmonary symptoms in the setting of increasing abdominal girth. Pulmonary function testing reveals decreases in functional residual capacity and total lung capacity.¹³⁰ Marked improvement in pulmonary function results from medical management of ascites, large-volume paracentesis, and thoracentesis.^{131,132} These interventions decrease the work of breathing and relieve symptoms. With control of ascites, even in the presence of pleural effusions, no other interventions may be necessary. For patients refractory to the above measures, second- and third-line strategies such as TIPS, indwelling pleural catheter placement, and pleurodesis have been described,

although liver transplantation should be pursued in these patients for definitive management.¹³²

HPS occurs in patients with mild to severe hepatic disease and in approximately 10% to 50% of patients with hepatic dysfunction.^{133,134} Diagnostic criteria for HPS in patients with cirrhosis include $\text{PaO}_2 < 80$ mm Hg or A–a gradient over 15 mm Hg in patients under 65 years old. The A–a gradient cutoff for patients over 65 is 20 mm Hg.¹³⁵ Other manifestations include platypnea (increased shortness of breath with movement from a supine to an erect position) and orthodeoxia (decreased oxygen tension on moving from a supine to an erect position). These two positional deficits in pulmonary function are related to the increased number of dilated capillaries in the basal areas of the lung; flow is increased in these vessels while the subject is standing, so that shunting is increased. Physical findings include clubbing and cyanosis of the nail beds and spider angiomas.

Although the underlying cause of hypoxemia in these patients is right-to-left intrapulmonary shunting, ventilation–perfusion mismatch and impaired hypoxic vasoconstriction also play a role. Patients usually present with dyspnea and worsening hypoxemia without evidence of a primary pulmonary process. Initial diagnostic tools include pulse oximetry and arterial blood gas analysis. When significant hypoxemia is found, pulmonary function testing is useful to rule out obstructive or restrictive airway disease. A definitive diagnosis can be obtained by the use of contrast-enhanced echocardiography (bubble study) or technetium-macroaggregated albumin (MAA) scanning, which will confirm the presence of intrapulmonary vascular dilation.^{136,137} Contrast echocardiography is the most sensitive test, whereby intrapulmonary vascular dilation is demonstrated by a late appearance of microbubbles in the left heart three to six cardiac cycles after injection.¹³⁸ MAA scanning is complementary to contrast echocardiography in the setting of coexisting intrinsic lung disease with severe hypoxemia, where MAA shunting of $> 6\%$ suggests HPS as the major contributor to hypoxemia.¹³⁹ The only effective therapy for this disease is orthotopic liver transplantation, and those with HPS and with a $\text{PaO}_2 < 60$ mm Hg receive extra priority at listing.¹³⁸

POPH is defined as a mean pulmonary arterial pressure of greater than 25 mm Hg, pulmonary artery occlusion pressure < 15 mm Hg, and pulmonary vascular resistance > 240 dyn/s/cm⁻⁵ on right heart catheterization in the setting of documented portal hypertension.¹³⁵ It is a relatively rare ($< 10\%$) complication of cirrhosis that, when severe, carries a substantial risk of mortality and is a relative contraindication to liver transplantation.^{140,141} Screening of patients with cirrhosis by Doppler echocardiography will reveal evidence of elevated right heart pressures, which need to be confirmed by right heart catheterization. Although the high flow state of cirrhosis can elevate right-sided pressures, fixed obstruction of the pulmonary microcirculation is highly lethal and is not likely to improve with liver transplantation. The exact pathophysiology behind POPH is not known, but portal hypertension is a necessary component of the disease process. The hyperdynamic state in portal hypertension may be the main contributory factor, although the severity of POPH does not correlate with the severity of portal hypertension.¹⁴² Treatment with prolonged intravenous infusion of prostaglandins has been shown to be effective in improving pulmonary hemodynamics but does not prolong survival.¹⁴¹ The most commonly used drugs in POPH are oral endothelin receptor antagonists such as bosentan and ambrisentan. As stated above, severe POPH (mPAP > 50 mm Hg) is an absolute contraindication to liver transplantation. For patients in whom medical therapy can maintain mPAP under 35 mm Hg and PVR under 400 dyn/s/cm⁻⁵, priority listing for liver transplantation is available.¹⁴³

Hepatic Encephalopathy

7 Etiology. Hepatic encephalopathy is a neuropsychiatric syndrome that occurs in the setting of hepatic disease. It is characterized by variable alterations in mental status, ranging from deficits detectable only by detailed psychometric tests to confusion, lethargy, and ultimately frank coma. The disease may present in association with acute hepatic failure, as a consequence of progression of chronic liver disease, or after the creation of a surgical portosystemic shunt. Usually, a precipitating cause, such as an acute variceal hemorrhage or infection, can be found.

The causative agent in hepatic encephalopathy has been the subject of much debate. Most evidence implicates ammonia in the development of this condition. Ammonia is produced during the bacterial digestion of proteins in the gut, is absorbed into the portal circulation, and usually undergoes extensive degradation in the liver.¹⁴⁴ Most researchers believe that encephalopathy is caused by products, such as ammonia, derived from the gastrointestinal tract that are usually metabolized by the liver. These agents reach the peripheral circulation as a result of poor hepatic metabolism or through portosystemic shunts that may be physiologic or the result of surgical procedures. In patients with cirrhosis, in addition to the accumulation of ammonia in the blood, the permeability of the brain to ammonia appears to be

increased.¹⁴⁵ Other suggested etiologic agents for hepatic encephalopathy include γ -aminobutyric acid (GABA), endogenous benzodiazepines,¹⁴⁶ branched-chain amino acids (BCAAs) (e.g., tryptophan),¹⁴⁷ neurotoxic short-chain fatty acids, mercaptans, phenols,¹⁴⁸ and endogenous opiates.¹⁴⁹

The following observations suggest that ammonia is the key mediator in hepatic encephalopathy: (a) ammonia levels are increased in 80% to 90% of patients with the condition,¹⁵⁰ (b) factors that precipitate hepatic encephalopathy cause increases in ammonia levels, and (c) treatments that relieve hepatic encephalopathy lower ammonia levels.¹⁵¹ Arguments against this hypothesis include the following: (a) levels of ammonia correlate poorly with the severity of hepatic encephalopathy, (b) high ammonia levels alone do not cause encephalopathy, (c) administration of ammonia to patients with cirrhosis but not hepatic encephalopathy does not cause encephalopathy, and (d) treatments that reduce ammonia levels also reduce the levels of other putative toxins.¹⁵¹

Clinical Features. A wide range of neurologic symptoms may occur in patients with hepatic dysfunction. Subtle deficits may include changes in personality, memory loss, alterations in sleep patterns, and minor decreases in intellectual function. Defects may be detectable only by detailed psychometric testing. If no known underlying liver disease is suspected, establishing the cause of an alteration in mental status may be difficult.

TREATMENT

Table 59-7 Treatment of Hepatic Encephalopathy

Identify precipitating factors
Disordered carbohydrate metabolism
Narcotics
Infection
Hypotension
Hypoxia
Excess exogenous protein
Gastrointestinal bleeding
Electrolyte abnormalities
Alkalosis
Supportive therapy
Eliminate dietary nitrogen
Purge gastrointestinal tract to remove blood and other nitrogenous compounds
Nonabsorbable antibiotics (neomycin or metronidazole)
Lactulose or lactitol
Dopamine receptor agonists
L-dopa and bromocriptine ^a
Branched-chain amino acid ^b
Temporary liver support
Orthotopic liver transplantation

^aArousal effect in selected patients may be secondary to enhanced renal function.

^bHigh cost and equivocal benefits of intravenous amino acid mixtures make it difficult to justify routine use.

With progression of disease, asterixis, a rapid repetitive flexion–extension of the wrist that occurs in response to sustained extension of the forearm and fingers, may occur. In addition, stigmata of liver disease are usually evident, including fetor hepaticus and spider angiomas. The combination of asterixis, elevated ammonia levels, and altered mental status in a patient with known liver disease strongly suggests the diagnosis. Electroencephalographic changes are nonspecific and may occur in patients with a variety of other conditions.

Factors that commonly precipitate hepatic encephalopathy include impaired renal function, variceal hemorrhage, constipation, infection, excessive dietary protein, and drugs, especially benzodiazepines and barbiturates.

Treatment. Treatment options for hepatic encephalopathy include correction of the precipitating factors, alterations in diet, bowel cleansing, medications that reduce ammonia production and neutralize its effects, and medications to treat possible neurotransmitter and nutrient deficiencies.

A search for precipitating factors is imperative and includes cultures of urine, sputum, and ascitic fluid; determination of electrolyte abnormalities; screening for viral infection; assessment of overall volume status; drug history; and endoscopy (Table 59-7).

Therapy begins with a trial of volume expansion via intravenous hydration to relieve azotemia and

reduce concentrations of toxic substances by dilution. The mainstays of treatment are directed at the removal of nitrogenous compounds from the gut. Most ammonia is produced within the small and large bowels by bacterial metabolism of dietary and endogenous protein. Orally administered cathartics and enemas are the best methods to achieve bowel cleansing. While dietary restriction of protein intake was once a mainstay in the therapy of hepatic encephalopathy, the loss of skeletal muscle, which aids in breakdown of ammonia, is now recognized as an important contributor to hepatic encephalopathy. Current recommendations thus favor regular or increased protein diets along with medical therapy for hepatic encephalopathy. Since patients with cirrhosis often manifest a deficiency of BCAAs compared to aromatic amino acids (which worsen hepatic encephalopathy); supplementation with BCAAs has been shown to improve the rate of recovery from episodic hepatic encephalopathy.¹⁵² L-carnitine supplementation has also been demonstrated to improve cognitive deficits and reduce ammonia levels.¹⁵³

The cathartic of choice is lactulose, a nonabsorbable disaccharide that reaches the distal ileum and colon essentially unmetabolized. Many theories regarding the mechanism of action of lactulose have been proposed. Initially, the presumed mechanism of action was that on reaching the colon, lactulose is metabolized by colonic bacteria to acidic products that lower the pH of the colon. Lowering the pH inhibits the growth of ammonia- and urea-producing bacteria and promotes the growth of *Lactobacillus*, a bacterium with little proteolytic activity.¹⁵⁴ The validity of this theory has been questioned. It appears now that lactulose alters the metabolism of intestinal bacteria by providing carbohydrate, which enhances the bacterial uptake of ammonia.¹⁵⁵ Combined with the osmotic diarrhea caused by the cathartic activities of lactulose, this effect leads to an increased excretion of ammonia.

The dosage of lactulose, 45 to 90 g/d, is administered orally, divided into 3 or 4 doses. The dosage can be adjusted to produce two or three soft stools daily. Hourly doses of 30 to 45 mL can be used to induce more rapid improvement during the initial phase of therapy. Symptoms usually abate within 24 hours, but more than 48 hours may be required. Doses can be adjusted if side effects such as flatulence, diarrhea, and electrolyte abnormalities occur.

Nonabsorbable antibiotics have also been used to decrease the number and concentration of ammonia-forming bacteria in the gut. Most experience has accrued for neomycin and metronidazole. These antibiotics are active against gram-negative anaerobes such as *Bacteroides*, which are considered to be a major source of ammonia production.^{156,157} The dosage of neomycin, 2 to 8 g/d, is divided into 4 doses and is continued for 4 to 10 days. Multiple double-blinded, randomized trials have determined the efficacy of antibiotics alone or in combination with lactulose. For acute hepatic encephalopathy, studies have shown that neomycin for 4 days is equally as effective as lactulose,¹⁵⁷ and metronidazole for 7 days is as effective as neomycin.¹⁵⁸ In addition, for chronic hepatic encephalopathy, neomycin for 10 days was equal to lactulose.¹⁵⁴

Due to the risk of nephrotoxicity and irreversible ototoxicity, neomycin therapy has fallen out of favor.¹⁵⁹ Rifaximin, a minimally absorbed macrolide antibiotic, was approved by the FDA in 2013 for the maintenance therapy of hepatic encephalopathy and is now frequently used in an off-label fashion for acute episodes as well. In a recent randomized controlled trial, the addition of rifaximin to lactulose resulted in a higher proportion of patients experiencing complete reversal of hepatic encephalopathy (76% vs. 50.8%) and decreased mortality (23.1% vs. 49.1%) compared to lactulose and placebo.¹⁶⁰ Thus, based on the most current evidence, the treatment of overt hepatic encephalopathy should consist of treatment of precipitating factors, followed by lactulose administration. Rifaximin should be added for patients without improvement in the first 24 hours. Following an episode of overt hepatic encephalopathy, maintenance therapy with lactulose and/or rifaximin should be administered indefinitely for secondary prophylaxis.¹⁵⁹

PORTAL HYPERTENSION

8 Portal hypertension is defined as a portal vein pressure above the normal range of 5 to 8 mm Hg. Portal hypertension may also be defined by the hepatic vein–portal vein pressure gradient, which is greater than 5 mm Hg in portal hypertensive states.¹⁶¹ Pressures in the portal venous system are usually measured indirectly via the wedged hepatic venous pressure utilizing a technique similar to that used to determine pulmonary capillary wedge pressure by pulmonary arterial (Swan–Ganz) catheterization.

Anatomy

The venous anatomy of the portal system is relatively constant, with the “usual” anatomy present in 98% of the population (Fig. 59-5). The portal vein is formed by the confluence of the superior mesenteric and splenic veins behind the neck of the pancreas. The inferior mesenteric vein most often joins the splenic vein before the portal vein is formed, but approximately one-third of the time the inferior mesenteric vein joins the superior mesenteric vein. The superior mesenteric vein may not be present, and the portal vein may be formed by multiple small branches from the mesenteric system that join the splenic vein.

Many branches of the portal venous system are affected when portal pressure rises. As pressure increases, blood flow decreases and the pressure in the portal system is transmitted to its branches. This transmission of pressure through branches of the portal system is beneficial in that it decreases overall portal pressure. It also is responsible for many of the complications of portal hypertension, however, because of the resulting dilation of venous tributaries.

The coronary or left gastric vein becomes highly significant in portal hypertension, by diverting portal blood to the veins of the lesser curve of the stomach and the esophagus, leading to the formation of varices. Other important collaterals include the inferior mesenteric vein, which connects with its rectal branches, which, when distended, form hemorrhoids; the umbilical vein in the ligamentum teres of the falciform ligament, which joins the left portal vein and causes abdominal wall veins around the paraumbilical plexus to dilate (caput medusae); the short gastric veins, branches of the splenic vein, which communicate with gastric veins and contribute to gastric varices; and the retroperitoneal veins of Retzius, which communicate with the gastrointestinal veins through the bare areas of the liver where no peritoneal layer separates the abdominal viscera from the retroperitoneum. The retroperitoneal collaterals can also form large splenorenal shunts that may decompress the portal system but are associated with severe encephalopathy.

Physiology

As in any vascular bed, portal hypertension is the product of blood flow and resistance. In nearly all cases, portal hypertension is caused by increased resistance to portal blood flow secondary to cirrhosis, portal vein thrombosis, or hepatic venous obstruction, though in rare instances, an arterioportal fistula may cause flow-related hypertension. Normally, the liver offers little resistance to portal flow because of the porous nature of the hepatic sinusoids and the capacity of the organ to expand. Moreover, the liver has limited control over portal blood flow; it is primarily a passive recipient of splanchnic flow, the primary regulation of which occurs at the level of the splanchnic arterioles.¹⁶² As discussed earlier, the deposition of collagen in the space of Disse (capillarization), in addition to the contractile properties of stellate cells, causes an increased resistance to portal blood flow in cirrhosis. In addition, various cytokines and hormones contribute to elevated portal pressures by inducing splanchnic vasodilation and an increase in splanchnic flow.

The increased blood flow through collateral vessels and subsequently increased venous return cause the characteristic hemodynamic features of portal hypertension, which include an increase in cardiac output and total blood volume and a decrease in systemic vascular resistance.¹⁶³ Arteriovenous shunts within the liver, stomach, and small intestine contribute to the augmented venous return and decreased peripheral vascular resistance. Early in the course of portal hypertension, blood pressure may be normal, but with progression of disease, blood pressure usually falls.¹⁶⁴

Figure 59-5. Potential venous collaterals that develop with portal hypertension. The veins of Sappey drain portal blood through the bare areas of the diaphragm and through paraumbilical vein collaterals to the umbilicus. The veins of Retzius form in the retroperitoneum and shunt portal blood from the bowel and other organs to the vena cava.

The portal venous concentration of nitric oxide, a potent vasodilator, has been shown to be elevated in patients with cirrhosis and portal hypertension.¹⁶⁵ In addition to nitric oxide, many other vasodilators are elevated in portal hypertension, including prostacyclin, endotoxin, and glucagon.¹⁶⁶

Etiology

Many pathologic processes can cause portal hypertension ([Table 59-8](#)). These are usually classified as prehepatic, hepatic, or posthepatic (presinusoidal, sinusoidal, or postsinusoidal) conditions. As noted above, in prehepatic and posthepatic conditions, portal hypertension is the result of mechanical venous obstruction at the level of the portal or hepatic veins, respectively, whereas cirrhosis is the main cause of hepatic portal hypertension.

Budd–Chiari Syndrome and Veno-occlusive Disease

The BCS is caused by hepatic venous obstruction. The name of the syndrome is derived from two investigators, the first of whom (Budd)¹⁶⁷ described the classic presentation of abdominal pain, ascites, and hepatomegaly, and the second of whom (Chiari)¹⁶⁸ described the pathologic characteristics of the liver. The obstruction may occur at the level of the inferior vena cava, the hepatic veins, or the central veins within the liver itself and may be the result of congenital webs (most common in Africa and Asia), acute or chronic thrombosis (most common in the West), and malignancy. With occlusion of the hepatic veins, pressure increases in the central veins. As a result, centrilobular congestion, necrosis, and, with chronic disease, fibrosis and cirrhosis with portal hypertension develop.

In the West, the most common causes of this syndrome are hypercoagulable states associated with polycythemia vera, myeloproliferative disorders, paroxysmal nocturnal hemoglobinuria, and defects in the coagulation cascade, as in conditions associated with high estrogen levels (e.g., pregnancy, use of birth control pills).^{169,170} Neoplasms may cause hepatic venous obstruction by direct invasion and occlusion of the vessels, or by establishment of a prothrombotic milieu secondary to the malignancy itself. In the East, the major causes of obstruction of the vena cava and hepatic veins are membranous webs that directly occlude the vessels. The etiology of vena cava webs is unknown. Veno-occlusive disease is characterized by obliterative endophlebitis of the intrahepatic veins ([Table 59-3](#)). Causes of veno-occlusive disease include medications, toxins, and pyrrolizidine alkaloids.

BCS may present with acute, subacute, or chronic symptoms and is often misdiagnosed. This is

unfortunate, because early treatment will prevent the development of hepatic fibrosis, which can lead to end-stage liver disease. Nearly 50% of patients have had symptoms for more than 3 months.¹⁷¹ Acute symptoms include hepatomegaly, right upper quadrant abdominal pain, nausea, vomiting, and ascites. In the chronic form of the disease, patients may present with the sequelae of cirrhosis and portal hypertension, including variceal bleeding, ascites, spontaneous bacterial peritonitis, fatigue, and encephalopathy. In the chronic form, the entire liver atrophies except for the caudate lobe, which may hypertrophy because its hepatic vein(s) enters the vena cava separately, so that venous outflow is not impeded.¹⁰⁰ The hypertrophy of the caudate lobe creates a longitudinal narrowing of the retrohepatic vena cava, which is surrounded by parenchyma, leading to secondary obstruction of the caval flow in the abdomen.

ETIOLOGY

Table 59-8 Common Causes of Portal Hypertension

Disorders That Primarily Increase Resistance to Flow
<i>Prehepatic</i>
Congenital atresia
Extrinsic compression
Schistosomiasis
Portal, superior mesenteric, or splenic vein thrombosis
<i>Hepatic</i>
CHRONIC-CIRRHOTIC
Hepatitis B, C
α_1 -Antitrypsin deficiency
Cryptogenic
Cystic fibrosis
Hemochromatosis
Nutritional (alcoholic)
Wilson disease
CHRONIC-NONCIRRHOTIC
Congenital hepatic fibrosis
Focal regenerative hyperplasia
Hepatic veno-occlusive disease
Idiopathic
Metastatic carcinoma
Sarcoidosis
Toxin and drug injuries
ACUTE DISEASE
Acute fatty liver
Alcoholic hepatitis
Fulminant hepatic failure
<i>Posthepatic</i>
Budd-Chiari syndrome
Chronic heart failure
Constrictive pericarditis
Vena cava webs
Disorders That Primarily Increase Flow
Hepatocellular carcinoma
Mesenteric arteriosclerotic or aneurysmal vascular disease
Osler-Weber-Rendu syndrome
Splenomegaly

Although the diagnosis can be made by ultrasonographic evaluation of the liver and its vasculature with a sensitivity of 85% to 95%,¹⁶⁹ cross-sectional imaging is essential for staging and planning therapy. Duplex scanning may reveal the location of the obstruction and characterize the flow within the vena cava and hepatic, portal, mesenteric, and splenic veins. Other common ultrasonographic findings consistent with BCS include lack of visualization of the hepatic veins, an enlarged caudate lobe with compressed inferior vena cava, enlarged intrahepatic collaterals, splenomegaly, and ascites.¹⁰¹ Thrombus within the hepatic veins or inferior vena cava may be directly visualized using contrast-enhanced magnetic resonance angiography (MRA).¹⁷²

Because the vascular obstruction is usually well established at the time of presentation, anticoagulation alone is rarely sufficient therapy for BCS. Although major open surgery has been favored in the past, including mesoatrial shunting,^{173,174} and even liver transplantation,¹⁷⁵ minimally invasive approaches are now preferred.¹⁷⁶ The mainstay of therapy is mechanical decompression with a side-to-side portosystemic shunt, optimally achieved with a percutaneous portacaval shunt (see below).

After shunt placement, the pressure on the vena cava by the caudate lobe is gradually relieved, leading to restoration of liver function.

A more direct solution, which is necessary in the face of complete caval obstruction, is the creation of a mesoatrial shunt, which was described by Cameron and Maddrey.¹⁷³ This radical procedure has been largely supplanted by percutaneous portacaval shunting (TIPS). The rates of postprocedural encephalopathy are usually not increased in patients with BCS, because they have anatomically healthy livers that recover fully if decompression is achieved early prior to the establishment of cirrhosis. In patients with end-stage liver disease, liver transplantation may be performed.¹⁷⁵ The 5-year survival rate for patients with good hepatic function before the shunt procedure is approximately 60%, with a 34% to 88% survival for patients after liver transplantation.¹⁷⁷ Postoperatively, patients are treated with long-term anticoagulation to prevent recurrent thrombosis.

As noted, minimally invasive treatment using TIPS may be first-line therapy, and it has supplanted surgical shunting in our practice.^{178,179} Case reports and small series have suggested efficacy for this technique,¹⁸⁰ and a recent larger study has indicated 1- and 5-year survival rates of 93% and 74%, respectively.¹⁸¹ Many patients develop shunt occlusion; however, further angiographic manipulation and long-term anticoagulation are required to maintain patency.

Portal Vein Thrombosis

Portal vein thrombosis is commonly associated with advanced cirrhosis, and may be the ominous portent of a HCC. Spontaneous portal vein thrombosis in the absence of cirrhosis is the cause of portal hypertension in fewer than 10% of adult patients but is the most common cause in children.^{182,183} In contrast to patients with cirrhosis-induced portal hypertension, these patients have normal liver function and are not as susceptible to the development of complications such as encephalopathy. Causes of portal vein thrombosis include umbilical vein infection (the most common cause in children), coagulopathies (protein C and antithrombin III deficiency), hepatic malignancy, myeloproliferative disorders, inflammatory bowel disease, pancreatitis, trauma, and previous splenorenal shunt.¹⁸⁴ Most cases in adults are idiopathic.

The diagnosis can be made by sonography, which reveals an echogenic lesion in the lumen of the portal vein and an absence of portal venous flow on duplex examination.¹⁸⁵ With time, cavernous transformation of the portal vein may occur, in which channels develop within the clotted portal vein.¹⁸² CT and MRI are also useful in establishing the diagnosis. Often, the initial manifestation of portal vein thrombosis is variceal bleeding in a noncirrhotic patient with normal liver function. Splenomegaly is another common finding.

The initial therapeutic option for the control of hemorrhage caused by portal vein thrombosis is esophageal variceal ligation. If unsuccessful, the distal splenorenal shunt has been the traditional surgical treatment for patients with isolated portal vein thrombosis. In patients whose intrahepatic portal vein is patent (most commonly children), however, a shunt created by placing an internal jugular vein graft between the superior mesenteric vein and the patent left portal vein within the parenchyma of the liver (Rex shunt) may be the optimal therapeutic procedure for reestablishing physiologic portal flow.¹⁸⁶ This is the most elegant solution for portal obstruction because the portal pressure is reduced by restoring blood flow to the liver, preventing chronic hepatic atrophy and dysfunction, which can occur in a patient with long-standing portal decompression. In fact, in our practice, the Rex shunt is the first-line treatment and we reserve splenorenal shunting for patients who have no remnant intrahepatic portal system to receive the shunted blood.

CLASSIFICATION

Table 59-9 Child–Turcotte Criteria for Hepatic Functional Reserve

Criterion	Class A	Class B	Class C
Encephalopathy	None	Minimal	Advanced
Ascites	None	Easily controlled	Poorly controlled
Bilirubin (mg/dL)	<2	2–3	>3
Albumin (g/dL)	>3.5	3–3.5	<3
Nutrition	Excellent	Good	Poor, “wasting”
Child–Turcotte–Pugh Grading of Severity of Liver Disease			
Score	1	2	3
Encephalopathy	None	1 or 2	3 or 4
Ascites	None	Mild	Moderate
Bilirubin (mg/dL)	1–2	2.1–3	≥3.1
Albumin (g/dL)	≥3.5	2.8–3.5	≤2.7
Prothrombin time (s)	1–4	4.1–6	≥6.1
or INR	<1.7	1.7–2.3	>2.3
Grade A, 5–6; grade B, 7–9; grade C, 10–15			

INR, international normalized ratio.

Splenic Vein Thrombosis

Splenic vein thrombosis is most often caused by disorders of the pancreas, including acute and chronic pancreatitis, trauma, pancreatic malignancy, and pseudocysts. This association is related to the location of the splenic vein behind and close to the pancreas. Other causes include retroperitoneal masses, abscesses, and inflammatory bowel disease; the remaining cases are idiopathic. Gastric varices are present in approximately 80% of patients, and esophageal varices in 30% to 40%.¹⁸⁷ Isolated “sinistral” or left-sided portal hypertension occurs in the setting of normal liver function, and patients are readily cured with splenectomy, although observation for asymptomatic patients is acceptable. The main indication for splenectomy is variceal hemorrhage.

Complications of Portal Hypertension

9 The most important complications of portal hypertension are gastrointestinal bleeding secondary to esophageal and gastric varices, ascites, and hepatic encephalopathy. The mortality risk associated with portal hypertension is primarily related to the functional status of the cirrhotic liver. Child introduced a scoring system of liver function for the purposes of assessing prognosis after portosystemic shunt surgery in patients with cirrhosis, which has been subsequently modified several times to the *Child–Turcotte–Pugh (CTP) score* (Table 59-9). These indices incorporate clinical and laboratory data as a means to assess the functional status of the liver, estimate hepatic reserve, and predict morbidity and mortality. They had been adopted by the United Network for Organ Sharing (UNOS) as a tool for stratifying pretransplant mortality risk for patients on the waiting list for liver transplantation.¹⁸⁸ Over the last decade, the use of these criteria in transplant has been replaced by the model for end-stage liver disease (MELD) score, which uses serum bilirubin, creatinine, and the international normalized ratio (INR) to produce a surprisingly robust prediction of 90-day mortality for patients with cirrhosis on the transplant list.¹⁸⁹ Though the CTP score produces a more complete assessment of the patient, its use of subjective clinical elements in the score made it unreliable as a verifiable element in assessment compliance with center behavior in national organ transplant policy.^{190,191}

While the MELD score was initially developed for the prognosis of patients after TIPS, the CTP score has had long-standing use as a reliable predictor of mortality risk for shunt surgery and, by extension, mortality risk of patients with cirrhosis undergoing other types of abdominal surgery.^{192,193} Patients with normal function, termed “Child A,” have adequate hepatic reserve and survival rates similar to those of noncirrhotic patients, whereas Child C patients have mortality rates in excess of 50% and may not tolerate any intervention short of hepatic transplantation.

Varices

One of the most life-threatening complications of portal hypertension is bleeding from esophageal varices. Esophageal varices are dilated veins found most commonly in the distal 5 cm of the esophagus. In the normal esophagus, a venous plexus is located in the submucosa; it becomes more superficially located to the lamina propria in the distal esophagus.^{194–196} This more superficial location in the distal esophagus is consistent with the known increased occurrence of bleeding varices in that location. In addition, 5% to 33% of patients with portal hypertension have gastric varices.¹⁹⁷

The pressure in the portal system is an important determinant of the likelihood for varices to develop. As noted earlier, portal pressure may be estimated from the hepatic vein wedge pressure, and the gradient between the wedge pressure and the free hepatic vein pressure is an indirect measure of the resistance across the liver. In general, varices do not develop in persons with hepatic vein–portal vein gradients below 12 mm Hg. Pressure gradients above 12 mm Hg are invariably present in patients with varices, but this pressure does not necessarily produce varices in all patients. Other, undetermined factors must play a role. Gastroesophageal varices are present in 40% of patients with Child A cirrhosis, and in up to 85% of patients with Child C cirrhosis.¹⁹⁸ Varices may also be present in chronic liver disease without outright cirrhosis. For example, 16% of patients with chronic hepatitis C and bridging fibrosis have varices.¹⁹⁹

In approximately 10% of all patients presenting with acute upper gastrointestinal bleeding, esophageal varices are the cause of bleeding. Rates of bleeding from varices vary among studies. In a study of the natural history of varices in which patients were prospectively followed for 6 years, esophageal varices developed in approximately 8% of patients with cirrhosis each year during the first 2 years of observation; the percentage increased to 30% by 6 years. Of the patients who had small varices detected at initial endoscopy, large varices developed in 25%.²⁰⁰ Other studies show an incidence of varices of up to 90% for patients with cirrhosis.^{201,202} Once varices are present, bleeding occurs in 25% to 35% of cases, with the highest risk occurring within the first year after diagnosis.^{202,203} Patients with large varices are at the highest risk for an initial bleed. Spontaneous bleeding from varices ceases spontaneously in up to 40% of patients, although mortality and recurrent bleeding remain high.¹⁹⁸ Of patients who survive an episode of bleeding, 30% experience rebleeding within 6 weeks, and 70% at 1 year.^{203,204} The correlation between severity of varices and derangement of hepatic function is inconstant, so mortality rates from bleeding varices range from 5% to 50%, with rates of 5%, less than 25%, and more than 50% for Child A, B, and C patients, respectively.²⁰⁴

The propensity for varices to bleed has been extensively studied. When combined with clinical data such as the presence of active alcohol consumption, certain endoscopic characteristics of varices have been correlated with initial episodes of bleeding (Table 59-10). These factors include variceal size, Child–Pugh class, and the presence of red wale markings (longitudinal dilated venules that resemble whip marks).²⁰² Direct and indirect measurements of portal pressure have been used to predict the likelihood of bleeding, with hemorrhage occurring only in patients with portal–hepatic venous gradients above 12 mm Hg.^{205,206}

TREATMENT

Table 59-11 Prevention/Treatment Options for Variceal Bleeding

Drug	Dose
Propranolol	10–20 mg bid titrated weekly to maximum of 160 mg bid
Nadolol	20 mg orally qd, titrated to reduction of HR by 20–25%, absolute HR of 55–60, symptoms
Isosorbide-5-mononitrate	20 mg orally tid
Vasopressin with nitroglycerin	0.4 U/min to maximum of 1.0 U/min, titrated to maintain SBP at approximately 100 mm Hg
Octreotide	50-mg bolus, followed by 50 mg/h for 5 d or until definitive treatment

HR, heart rate; SBP, systolic blood pressure.

Diagnosis of Varices and Prevention of Initial Variceal Bleeding. Because of the severe consequences of variceal bleeding, methods to diagnose varices prior to bleeding and to prevent first (primary prophylaxis) and recurrent (secondary prophylaxis) episodes of bleeding have been developed. Esophagogastroduodenoscopy (EGD) is the gold standard for the diagnosis of gastroesophageal varices, and should be performed in all patients upon the initial diagnosis of cirrhosis. If no varices are present upon initial screening, an EGD should be repeated in 2 to 3 years for patients with compensated cirrhosis. If small (<5 mm) varices are present, EGD should be repeated in 1 to 2 years. Patients with decompensated cirrhosis should undergo yearly screening EGD based on current recommendations from the AASLD.¹⁹⁸ After varices are diagnosed, methods of primary and secondary bleeding prophylaxis include control of the underlying cause of cirrhosis (i.e., alcohol consumption) and pharmacologic and surgical interventions to lower portal pressure. The next section discusses methods of primary prophylaxis to prevent initial episodes of bleeding (Table 59-11).

Beta Blockade. The use of nonspecific β -adrenergic blockade has been studied extensively in randomized controlled trials of the primary prophylaxis of variceal bleeding. The mechanism of action of these drugs (propranolol, nadolol) involves effects of both β_1 -adrenergic and β_2 -adrenergic blockades, including decreased cardiac output and increased splanchnic arteriolar vasoconstriction as a result of the loss of opposing β_2 -adrenergic dilation.^{206,207} The combined effects decrease portal blood flow and subsequently portal pressure.

These drugs are effective in portal hypertension associated with prehepatic, intrahepatic, and posthepatic conditions,²⁰⁸ regardless of whether ascites is present.²⁰⁹ Not all patients respond to therapy, however. Two meta-analyses have evaluated seven randomized controlled trials comparing propranolol or nadolol with placebo in the prevention of initial variceal bleeding. Both analyses concluded that beta blockade is significantly correlated with a reduced incidence of bleeding.^{210,211} A reduction of 40% was noted overall after all trial results were combined, with bleeding developing in approximately 16% of treated and 27% of untreated patients. The goal of therapy is to reduce the hepatic vein–portal vein gradient to below 12 mm Hg or to more than 20% below baseline.²¹² Patients who meet these goals not only have a lower risk of variceal bleeding, but also of developing ascites, spontaneous bacterial peritonitis, and death.²¹³ In addition to reducing the number of first episodes of bleeding, beta blockade therapy has been shown to reduce mortality in most clinical trials.²¹⁴ A meta-analysis of these studies concluded that mortality from bleeding is reduced in patients with large varices.

Despite their known benefits, beta blockers are also associated with significant side effects that limit their universal application in patients with cirrhosis. There is no role for beta blockade to prevent formation of varices in patients who do not already have them, based on a large randomized study by Groszmann et al.²¹⁵ In this study, serious adverse events were significantly more common in patients undergoing timolol therapy compared to placebo. For patients with small (<5 mm) varices without high-risk features (decompensated cirrhosis, red wale markings), current guidelines from the AASLD state that beta blockers may be used, although convincing evidence of substantial benefits in this setting is lacking.¹⁹⁸

Surgical Intervention. In the 1950s and 1960s, surgeons created prophylactic portosystemic shunts in an attempt to prevent variceal bleeding. These procedures were studied in a randomized controlled fashion and, although effective in preventing variceal bleeding, they caused an increased incidence of hepatic failure and encephalopathy and had no effect on overall survival.^{216,217} These results provided

clinical support for the notion that portal diversion accelerated the decline of liver function in patients with cirrhosis and they are no longer performed for this indication.

Endoscopic Sclerotherapy and Variceal Ligation. In the past, prophylactic sclerotherapy to prevent variceal bleeding was an accepted practice but technical challenges and esophageal and pulmonary complications have led to abandonment of endoscopic sclerotherapy (ES) for the primary prevention of variceal bleeding. Initial investigations of the effectiveness of endoscopic variceal ligation (EVL) as a method of primary prophylaxis to prevent initial bleeding in high-risk patients with esophageal varices reported mixed results.^{218,219} In one study, no statistically significant differences in the incidence of initial bleeding and mortality were found in a comparison of patients after variceal ligation with controls,²²⁰ though subgroup analysis revealed a significant decrease in the incidence of initial bleeding for Child–Pugh class B patients.²¹⁹ Furthermore, there seems to be a significant prognostic divergence related to variceal size. As data have accumulated, consensus recommendations regarding prophylaxis have emerged as presented in recent practice guidelines from the AASLD. Briefly summarized, patients with cirrhosis with small, low-risk varices should be managed with beta-blocker prophylaxis. In those with medium or large varices with high-risk features (Child B or C, red wale markings), either EVL or beta blockade is acceptable primary prophylaxis. In the absence of the above high-risk features, beta blockade is preferred, with EVL reserved for those patients who have contraindications to, or are intolerant of beta blockers.¹⁹⁸

Treatment of Esophageal Variceal Bleeding

Initial Management. Initial management of the patient with acute variceal bleeding includes the following: (a) establishment and maintenance of an airway; (b) hemodynamic monitoring; (c) placement of large-bore intravenous lines; (d) full laboratory investigation, including measurement of hemoglobin and hematocrit, coagulation profile, liver function tests, measurement of electrolytes, and assessment of renal function; (e) administration of blood products as needed, including packed red cells, platelets, and fresh frozen plasma; and (f) intensive care unit monitoring. Hemoglobin concentration should be maintained around 8 g/dL.^{221,222} Transfusion to higher hemoglobin concentrations has been associated with higher portal pressure and worse outcomes. Furthermore, as gastrointestinal bleeding is associated with a high risk of subsequent spontaneous bacterial peritonitis in patients with cirrhosis, a 7-day course of antibiotics (typically a quinolone such as norfloxacin or ciprofloxacin) is also recommended as standard therapy for acute variceal bleeding.²²³

Pharmacologic Therapy. The administration of vasoactive medications can be commenced almost immediately after patient presentation if the history and physical findings suggest variceal bleeding. This practice decreases the rate of bleeding and enhances the endoscopic ability to visualize the site(s) of bleeding.

Vasopressin (antidiuretic hormone) has potent splanchnic vasoconstrictive properties that decrease portal venous and collateral flow and reduce portal pressure. In randomized prospective trials, as well as in a meta-analysis, continuous intravenous administration of vasopressin has proved to reduce variceal bleeding, an observation initially made in 1962.^{224–226} When vasopressin was compared with placebo, bleeding stopped in an average of 52% of patients who received vasopressin and 18% of patients who received placebo. Rates of rebleeding as high as 45% were noted, however. Because of coronary vasoconstrictive effects, vasopressin is often used in combination with a vasodilator, such as nitroglycerin. The combination provides protection from adverse cardiac events and increases the effectiveness of vasopressin by decreasing intrahepatic and collateral resistance.²²⁷ A meta-analysis of three randomized controlled trials confirmed the increased effectiveness of vasopressin and nitroglycerin in comparison with vasopressin alone.²²⁸

Somatostatin and octreotide, its longer-acting eight-amino acid derivative, have been used extensively for the treatment of variceal bleeding. These agents decrease splanchnic blood flow indirectly by reducing the levels of other factors, such as glucagon, vasoactive intestinal peptide, and substance P, rather than by direct vasoconstriction.²²⁹ The effects of somatostatin are limited to the splanchnic circulation, so that side effects are minimized.²³⁰ A somatostatin and octreotide combination has proved to be as effective as vasopressin, sclerotherapy, and balloon tamponade in multiple studies.^{231–233} Because of the lack of complications related to somatostatin therapy, octreotide is the initial drug of choice for the treatment of acute variceal hemorrhage. Dosing typically consists of a bolus of 50 µg followed by an infusion of 50 µg/hr, to be initiated as soon as variceal bleeding is suspected and continued for 3 to 5 days after the diagnosis has been verified.¹⁹⁸

Endoscopic Interventions. Esophageal variceal ligation has become the principal approach to the initial control and ongoing treatment of variceal bleeding; it is performed at the bedside in acute bleeding and has replaced variceal sclerosis.

The technique of ligation ([Fig. 59-6](#)) includes placing an endoscope over a sheath (which allows multiple insertions and removal of the endoscope), suctioning of a varix into the lumen of a plastic channel, and then placing a rubber band around the tissue. The procedure is similar to the ligation of hemorrhoids. The tissue then sloughs in 1 to 3 days, leaving a shallow ulcer. Up to six bands can be placed at each session. Newer endoscopes allow for the placement of multiple bands without removal of the endoscope.

Success rates for variceal ligation range from 80% to 100%, in comparison with 77% to 94% for sclerotherapy, in controlled trials.²³⁴ In patients with profuse bleeding, however, the type of endoscope used for variceal ligation may make visualization of the bleeding varices difficult leading some investigators to choose sclerotherapy in these patients, and use variceal ligation once bleeding is somewhat controlled.

Balloon Tamponade. The vast majority of patients (75% to 90%) with bleeding esophageal varices respond to endoscopic or pharmacologic therapy. For patients who fail these interventions, balloon tamponade ([Fig. 59-7](#)) is an alternative therapy with a high success rate in controlling bleeding. It entails the placement of a specialized nasogastric tube with two balloons that can be inflated separately and to different pressures to apply direct compression to the gastroesophageal junction and the esophagus. Once the mainstay in the initial management of variceal bleeding, use of these tubes is becoming a lost art, most suitable for initial stabilization of patients in a facility with limited availability of endoscopic or radiologic support. Because these tubes are difficult to use, and may cause fatal complications with esophageal injury, it remains important for surgeons and gastroenterologists with responsibility for managing gastrointestinal bleeding to understand principles for safe use. The most commonly used tubes are the Sengstaken–Blakemore tube and the Minnesota tube. The former consists of a gastric balloon and an esophageal balloon with a sump port for gastric suctioning. The latter tube has an additional port above the esophageal balloon for the aspiration of saliva and other material from the esophagus and pharynx.

Figure 59-6. Endoscopic ligation of esophageal varices. The device used for ligation is based on the standard Barron-type ligator for the treatment of anal hemorrhoids. The esophageal varix is drawn up into the ligating device with suction (**A**), and the base of the varix is ligated with an O-ring (**B**). Up to six varices can be treated at a single session.

Figure 59-7. The Sengstaken–Blakemore tube is used to tamponade acutely bleeding gastroesophageal varices. The tube has three lumina—one to aspirate the stomach, another to inflate the gastric balloon, and a third to inflate the esophageal balloon. Patients treated with balloon tamponade should be in an intensive care unit, and endotracheal tubes should be placed in almost all to prevent aspiration.

Placement of these tubes begins with the establishment of a safe airway by endotracheal intubation. The tube is then passed through the nose and into the stomach. Radiographic confirmation that the tip of the tube is in the stomach is required before balloon inflation to prevent inadvertent intraesophageal inflation of the gastric balloon and resultant perforation. The gastric balloon is inflated with 200 mL of air and firmly pulled backward against the gastroesophageal junction to tamponade any proximal gastric bleeding. The esophageal balloon is then inflated to a pressure of 30 to 40 mm Hg, and the tube is secured to the patient by means of a facemask or helmet to ensure adequate stability of the tube and prevent inadvertent removal.

Because of the possible complications of balloon tamponade (e.g., aspiration, esophageal and gastric perforations, necrosis), which occur in 10% to 20% of patients, its use is restricted to approximately 24 hours. Success rates for cessation of bleeding are 70% to 80%, but more than half of all patients rebleed when the balloons are deflated. Although this method is highly effective in the initial control of bleeding, with an efficacy similar to that of pharmacologic agents, because of its transient effects it can be used only as a temporizing measure in anticipation of a more definitive procedure (e.g., TIPS, placement of a surgical shunt, or transplantation) and is used only after endoscopic and pharmacologic therapies have failed.

Transjugular Intrahepatic Portosystemic Shunt. In the 10% to 20% of patients who continue to bleed or who have early rebleeding, a shunt procedure (to bypass the high-pressure hepatic vascular bed) may be indicated ([Algorithm 59-1](#)). The mortality rate associated with failure to control bleeding can be as high as 90%, and surgically created shunts in this setting are associated with a high morbidity and mortality rate.

10 The TIPS ([Fig. 59-8](#)) has become first-line treatment for bleeding esophageal varices when the aforementioned attempts fail.²³⁵ Absolute contraindications to TIPS include congestive heart failure, uncontrolled sepsis, multiple hepatic cysts, severe pulmonary hypertension, and uncontrolled biliary obstruction. Relative contraindications include HCC, hepatic vein obstruction, severe coagulopathy or thrombocytopenia, and moderate pulmonary hypertension.²³⁶ After ultrasonographic confirmation of patency of the portal vein, the procedure is performed in the interventional radiology suite, where a wire-guided stent (8 to 12 mm in diameter) is placed percutaneously into the jugular vein. The wire is then guided through the superior vena cava, right atrium, and inferior vena cava into a hepatic vein, after which the catheter traverses the hepatic parenchyma and joins the hepatic vein to a portal vein. This connection effectively creates a side-to-side portacaval shunt. Success rates in the cessation of variceal bleeding are as high as 90% to 100%, with an incidence of recurrent bleeding of approximately 10%.^{237,238}

As discussed earlier, the ideal portosystemic shunt lowers the pressure in the portal system without

critically reducing liver perfusion, which may cause hepatic dysfunction and may accelerate the progression of cirrhosis. It is possible to readily measure the portal pressure during TIPS, and many authors have proposed these measurements as a guide to optimal management of the TIPS to balance control of bleeding with hepatic perfusion. To control bleeding, the therapeutic goal is to reduce the hepatic–portal venous pressure gradient to below 12 mm Hg. TIPS reduces the portosystemic pressure gradient to a mean of approximately 9 to 15 mm Hg (average, 10 mm Hg) or to 40% to 62% below baseline.^{239–241} A residual portal gradient less than 5 mm Hg has been associated with a deleterious impact on hepatic flow.²⁴² Earlier studies documented high mortality (40% to 60% at 6 to 7 weeks) despite the relative noninvasiveness of the procedure, reflecting the gravity of the clinical condition of most patients requiring this intervention. One potential cause of the high mortality is a delay in instituting TIPS until multiple unsuccessful attempts at sclerotherapy or banding have been made. Since well-validated instruments predict the survival of patients after TIPS, the procedure should be used with caution in patients with high MELD scores, though TIPS has been used successfully to bridge patients to transplantation.^{243,244} The use of TIPS in massive variceal bleeding in a patient with a high MELD score who has contraindications to liver transplant should be regarded as a palliative intervention.

Algorithm 59-1. Suggested treatment options, in order of preference, for patients who fail medical management for variceal bleeding.

Figure 59-8. Schematic representation of the steps used to create a transjugular intrahepatic portosystemic shunt. **A:** A needle is directed from the IVC or hepatic veins into an intrahepatic portal venous branch. **B:** A guidewire is advanced into the portal venous system. **C:** The resulting tract is then balloon dilated. **D:** A stent is then placed into the dilated tract. **E:** Completed TIPS shunt. *Arrows indicate direction of blood flow.*

As with all portosystemic shunts, a significant complication of TIPS is the development of hepatic encephalopathy. The rate of hepatic encephalopathy following TIPS is 34%, compared to 19% following EVL for acute variceal bleeding, although the use of covered stents has reduced the rate of post-TIPS encephalopathy from when bare metal stents were used primarily.^{245,246} Although in early series stenosis or occlusion of the stent developed in up to 50% to 60% of patients in the first year, long-term patency can be maintained by ongoing surveillance of the shunt with redilatation, as needed. Shunt stenosis is managed angiographically with thrombolytic therapy, dilation, or replacement of the stent. The newest shunts are lined with polytetrafluoroethylene (PTFE) and have a much higher patency than the original permeable wallstents. Primary patency rates are 76% to 89% with shunt dysfunction occurring in only 15% of patients at 1 year.²³⁶ Patients are usually followed at 3-month intervals by ultrasonography to assess the patency of the shunt. At 6 months of follow-up, 92% of patients had had no episodes of rebleeding, and 82% were free of hemorrhage at 1 year. It is safe to assert that the TIPS is now the standard procedure used to halt bleeding in patients who fail medical therapy. The ability to effectively decompress the portal circulation without open surgery in these critically ill patients has transformed clinical hepatology. Patients become medically stable and can be evaluated for transplantation electively. Patients with reversible liver disease (e.g., abstinent alcoholics) may recover fully without further intervention because the TIPS will slowly close as the liver heals.

Surgical Decompression

Background. Surgeons have been performing shunt procedures since the 1800s. The first was an end-to-

side portacaval shunt with ligation of the distal portal vein, performed by Nicolai Eck (Eck fistula) in dogs. In 1945, Whipple²⁴⁷ at the Columbia-Presbyterian Medical Center in New York performed this shunt for the first time for the indication of variceal bleeding. This group was also responsible for the development of the tube for the tamponade of bleeding esophageal varices, which adopted the name of Blakemore, as discussed previously.

11 Surgical interventions for the treatment of bleeding varices are divided into three main types: (a) liver transplantation, (b) shunt procedures, and (c) devascularization procedures. The only definitive procedure for the treatment of portal hypertension caused by cirrhosis is orthotopic liver transplantation, and the success of this option during the past two decades has revolutionized the treatment of portal hypertension and its complications in patients with end-stage liver disease. However, for the treatment of portal hypertension in patients without cirrhosis or in those whose liver function does not warrant a transplant (e.g., patients with portal vein thrombosis), decompressive surgically created shunts or devascularization procedures may be performed.

Shunts. Portosystemic shunts created operatively can be divided into three categories: (a) totally diverting (nonselective) shunts, (b) partially diverting shunts, and (c) selective shunts. Total shunts are created by completely bypassing the flow of blood away from the liver by joining the portal vein to the vena cava. Examples include the end-to-side portacaval shunt (Eck fistula) (Fig. 59-9) and the large-diameter (>10-mm) side-to-side portacaval (Fig. 59-10), mesocaval, and central splenorenal shunts. Because the pressure in the portal vein is much higher than that in the vena cava (or the renal vein), large side-to-side shunts divert all blood flow through the path of least resistance, so that flow in the portal vein is reversed, creating “hepatofugal” flow, out of the liver and decreasing total hepatic perfusion. One of the causes of ascites in patients with portal hypertension is high pressure at the level of the hepatic sinusoids with protein-rich fluid leaking directly out of the swollen liver. The main difference between end-to-side and side-to-side shunts is that maintenance of high pressure with end-to-side shunts may worsen ascites, whereas side-to-side procedures effectively relieve this problem by reducing sinusoidal pressure. Complete portal blood flow diversion lowers portal pressure and is highly effective in the treatment of bleeding esophageal varices but, as noted earlier, may accelerate hepatic decompensation.

Figure 59-9. End-to-side portacaval shunt, also referred to as an Eck fistula. The portal vein is divided, the hepatic limb of the portal vein is ligated, and the splanchnic end of the portal vein is anastomosed end to side to the vena cava. All portal blood is necessarily diverted into the vena cava, and the hepatic limb of the portal vein cannot serve as an outflow tract.

The main complications of totally diverting shunts are a worsening of liver function and hepatic encephalopathy as a result of decreased flow through the liver and loss of hepatotropic factors from the mesenteric venous system. Another disadvantage of portacaval shunts is that the porta hepatis must be dissected, so that future surgical procedures in the area (e.g., liver transplantation) are more difficult.

Partially diverting shunts allow for the maintenance of hepatopetal flow while decompressing the high pressures in the portal system. The original shunts were larger than 10 mm in diameter and were able to create a gradient between the portal vein and vena cava that maintained some prograde hepatic flow. All these shunts, however, dilated over time and became complete shunts in that the portal vein to inferior vena cava pressure gradient disappeared. The small-diameter (8-mm) side-to-side mesocaval (Fig. 59-11) and portacaval (Sarfeh) (Fig. 59-12) shunts are performed with an interposition graft made of either expanded PTFE or dacron. A significant component of the Sarfeh procedure is ligation of the coronary (left gastric), gastroepiploic, and other collateral veins. Bleeding from varices resolves in more than 90% of patients.^{248,249} This smaller-diameter shunt has a higher resistance than the larger shunt, is synthetic and therefore does not dilate, can maintain hepatic perfusion, and is associated with a lower incidence of hepatic encephalopathy. With these shunts, portal pressure gradients can be reduced to the critical 12 mm Hg while hepatopetal flow is maintained in up to 80% to 90% of patients. In addition, the maintenance of mesenteric pressure at or relatively close to normal levels may prevent the hyperammonemia associated with total shunts. One relatively common complication is graft thrombosis, which occurs in up to 16% of patients.²⁴⁹ Shunt thrombosis can usually be treated angiographically. Dissection at the porta hepatis leads to the formation of adhesions, which may compromise later liver transplantation.

Figure 59-10. Side-to-side portacaval shunt. An anastomosis is made between the side of the portal vein and the side of the inferior vena cava. With a shunt of standard diameter, almost all splanchnic blood is diverted around the liver into the low-pressure vena cava. The hepatic limb of the portal vein serves as an outflow tract from the liver toward the low-pressure vena cava.

Selective shunts are designed to create two separate drainage systems within the portal venous network. A high pressure is maintained within the mesenteric system and a low pressure is created in the esophagogastric system by shunting blood from the latter into the systemic circulation without decompressing the mesenteric network. The most traditional and most favored selective shunt is the distal splenorenal shunt (Fig. 59-13).²⁵⁰ The distal splenorenal shunt selectively decompresses the gastroesophageal venous system through an anastomosis between the distal end of the splenic vein and the side of the renal vein. Decompression occurs through the short gastric veins, which are in continuity with the splenic vein. In addition, as in the small side-to-side shunts described earlier, collateral veins must be ligated.

Figure 59-11. Interposition mesocaval shunt. A plastic prosthesis or an autogenous internal jugular vein is used for the shunt. One end is anastomosed to the inferior vena cava, and the other end is anastomosed to the trunk of the superior mesenteric vein. The shunt curves around the lower edge of the third portion of the duodenum and is sometimes called a C-shunt.

Advantages to this procedure are the following: (a) control of bleeding is excellent in more than 90% of patients, (b) no dissection of the porta hepatis is required, (c) hepatopetal flow is maintained, and (d) the incidence of encephalopathy (5% to 24%) and the risk of progressive liver failure are lower.²⁵¹ Experience with this shunt has revealed that most patients have hepatopetal flow, with 84% of alcoholic and 90% of nonalcoholic patients having prograde flow at 4 years after surgery.²⁵² Some loss of prograde portal flow does occur as a result of either portal vein thrombosis (approximately 10% of patients) or increased flow through collaterals located along the pancreas. This latter mechanism can be prevented by complete dissection of the splenic vein from the posterior aspect of the pancreas (splenopancreatic disconnection),²⁵³ but this additional technique adds to the complexity of the operative procedure and to the incidence of complications.

The distal splenorenal shunt is relatively contraindicated in patients with significant ascites. Because no portal venous decompression occurs, ascites may increase after a distal splenorenal shunt is created. In addition, ligation of collateral vessels and lymphatics during the procedure contributes to increased portal pressures and subsequent increase in ascites. Patients with small splenic veins (<8 mm) have a relatively high incidence of shunt thrombosis.

Several trials comparing side-to-side total shunts with the distal splenorenal shunt found that they are equally effective (>90%) in stopping variceal hemorrhage.²⁵⁴ The incidence of hepatic encephalopathy is lower after the distal splenorenal shunt, with rates of 36% and 15% for the total and selective shunts, respectively. Rates of rebleeding were similar and ranged from 0% to 30%, with no survival advantage for either procedure.

Figure 59-12. Small-diameter interposition portacaval Sarfeh shunt. A vascular prosthesis measuring 8 to 10 mm in diameter is interposed between the side of the vena cava and the side of the portal vein. The goal is to reduce portal pressure partially and thereby prevent variceal hemorrhage but still maintain sufficient pressure to permit the prograde flow of portal blood to the liver. This procedure is simpler to perform than that for the Warren shunt and theoretically avoids the problem of diversion of an increasing proportion of portal blood away from the liver over time, as occurs with the Warren shunt.

Figure 59-13. Distal splenorenal Warren shunt. The splenic vein is divided near its junction with the superior mesenteric vein. The distal end of the splenic vein is anastomosed to the renal vein. Varices are selectively decompressed through the stomach and short gastric veins into the splenic vein and then into the vena cava through the renal vein. Portal hypertension is maintained in the portal and superior mesenteric veins to provide enough pressure to drive portal blood through the diseased liver.

Figure 59-14. Transection and reanastomosis of the distal esophagus with the stapling device to control variceal hemorrhage. **A:** A stapling device is inserted through a small gastrotomy incision. **B:** When the device is fired, the esophagus is simultaneously transected and reanastomosed with staples. **C:** If the device fires correctly, a complete ring of esophageal tissue is excised.

Investigators have also used the side-to-side nonselective total shunt for the emergency treatment of bleeding varices. Bleeding stopped in more than 90% of patients with medical therapy alone, although bleeding often restarted shortly thereafter. Bleeding stopped in all patients after surgery, and 99% of patients were completely free of episodes of rebleeding. The 5-year survival was approximately 80%, with the majority of deaths occurring during the first year after surgery as a result of progressive hepatic failure. Hepatic encephalopathy requiring recurrent intervention, including dietary restriction and lactulose or neomycin therapy, occurred in 8% of patients. These data support an aggressive, systematic approach to caring for these patients before, during, and after surgery, though most of these patients had alcoholic liver disease, which recovers rapidly with withdrawal of the alcohol.

Devascularization Procedures. Devascularization procedures are nonshunting techniques in which the venous drainage of the stomach and esophagus is disconnected from the liver and intestinal vessels. These procedures are relatively less technically demanding than shunting procedures and can be performed in patients with extensive portal thrombosis who preclude other options. They do not interfere with hepatopetal blood flow and therefore do not increase the incidence of hepatic encephalopathy.

The procedures range in complexity from simple esophageal transection and reanastomosis with an end-to-end anastomosis (EEA) stapler combined with ligation of the coronary vein (Fig. 59-14) to the Sugiura procedure (Fig. 59-15). The Sugiura procedure requires both abdominal and thoracic incisions, through which a splenectomy, devascularization of the proximal stomach and esophagus, transection of

the esophagus with reanastomosis, and ligation of all gastroesophageal collaterals are performed.²⁵⁵ The latter procedure can also be performed via a single abdominal incision.²⁵⁶ Bleeding recurs in fewer than 5% of patients in Japan, but rates of rebleeding range from 10% to 54% in other countries.²⁵⁷ Operative mortality rates range from 10% to 35% and outcomes are certainly related to the severity of liver disease. In our practice, these procedures are not used in patients with liver disease, but exclusively in patients with diffuse portomesenteric thrombosis, in whom decompressive shunts cannot be made.

Figure 59-15. Sugiura esophageal transection and devascularization operation.

Hepatic Transplantation. Liver transplantation is the definitive therapy for portal hypertension and cirrhosis and the complications thereof, but is indicated for the overall management of end-stage liver disease and has no role in the control of acute variceal bleeding. When successful, transplantation treats both the underlying disease and any acute complication.

In conclusion, open surgical intervention short of liver transplantation for patients with cirrhosis and portal hypertension is becoming a rarity. With the advent of TIPS, the indications for surgically created shunts are dwindling. Although some studies have shown an increased need for reintervention in patients who have undergone TIPS for variceal bleeding, the overwhelming efficacy and safety of TIPS has essentially settled the issue and today, even in large liver centers, open portal decompressive procedures are rarely performed.

Current guidelines recommend nonselective beta blockade at the maximally tolerated dose for secondary prophylaxis, followed by serial EVL until all varices are obliterated. Patients should then undergo surveillance EGD every 6 to 12 months to evaluate for recurrent varices. TIPS should be reserved for Child A or B patients who bleed again despite combination medical and endoscopic therapy. Shunt surgery remains an option for good risk Child A patients. Those patients who are candidates should be referred to a transplant center for timely evaluation.¹⁹⁸

Gastropathy and Gastric Varices. Approximately 10% of patients with esophageal varices also have gastric varices. Conversely, about 90% of patients with gastric varices have esophageal varices.¹⁹⁷ Bleeding from gastric varices occurs in approximately 25% of affected patients and is usually more severe than bleeding from esophageal varices. Rebleeding occurs in up to 30% of patients after an initial bleed.²⁵⁸ The same pharmacologic interventions used for esophageal varices are used to treat gastric varices. However, sclerotherapy and EVL have proven relatively ineffective for bleeding gastric varices, and endoscopic variceal obliteration with tissue adhesives such as N-butyl-cyanoacrylate or isobutyl-2-cyanoacrylate has shown better rates of initial hemorrhage control and prevention of recurrent bleeding. A large randomized controlled trial demonstrated better prevention of rebleeding following acute gastric variceal hemorrhage with N-butyl-cyanoacrylate compared to EVL.²⁵⁹ Balloon tamponade may also be used as a temporizing measure while arrangements for definitive therapy are made. TIPS is the primary therapy for controlling gastric varices in patients who fail or cannot receive endoscopic therapy, with bleeding control rates of over 90% reported.¹⁹⁸ The distal splenorenal shunt is reserved

for the rare patient who cannot receive TIPS.

Portal hypertensive gastropathy is a condition characterized by dilation of the venules and capillaries of the gastric mucosa without associated inflammation. The major complication of gastropathy is bleeding; gastropathy accounts for 4% to 38% of all episodes of acute bleeding in patients with cirrhosis.²⁶⁰ TIPS may provide therapeutic decompression in this setting as well.

Ascites

One of the most important consequences of hepatic dysfunction in cirrhosis and portal hypertension is ascites. This development portends a significant worsening of the patient’s condition, with markedly decreased survival rates. Ascites is defined as the accumulation of free fluid within the abdominal cavity (normally <150 mL). Causes of ascites are listed in Table 59-12. In cirrhosis, the fluid is derived from a combination of hepatic (high in protein) and splanchnic (low in protein) lymphs that cannot be absorbed as a result of the increased hydrostatic pressures within the liver and splanchnic systems secondary to cirrhosis and capillarization of the space of Disse.²⁶¹ Because of the loss of sinusoidal fenestrations and a subsequent decrease in their permeability, splanchnic lymph is more abundant than hepatic lymph in patients with advancing cirrhosis, so that the protein content of ascitic fluid is relatively low.²⁶² The main underlying pathophysiology in the development of ascites is renal sodium retention and associated water retention, which lead to fluid overload. Peripheral vasodilation and lower pressures are thought to be secondary to the dilator effects of nitric oxide, glucagon, and prostaglandins on nascent arteriovenous shunts present throughout the splanchnic vascular system, as well as in muscle, skin, and brain. The severity of liver disease is not uniformly correlated with the presence or absence of ascites.

DIAGNOSIS

Table 59-12 Differential Diagnosis of Ascites

Portal Hypertension
Cirrhosis and other intrahepatic diseases
Hepatic congestion
Congestive heart failure
Constrictive pericarditis
Inferior vena cava obstruction
Budd–Chiari syndrome
Portal vein occlusion
Hypoalbuminemia
Nephrotic syndrome
Protein-losing enteropathy
Malnutrition
Miscellaneous Disorders
Myxedema
Ovarian disease (Meigs syndrome, struma ovarii)
Peritoneal carcinomatosis
End-stage renal disease
Chylous ascites
Bile ascites
Urine ascites

From Sleisenger MH, Fordran JS. *Gastrointestinal Disease: Pathophysiology, Diagnosis and Management*. 4th ed. Philadelphia, PA: WB Saunders; 1989:433.

Clinical and Laboratory Features. Ascites may be present in patients with cirrhosis who have no other overt signs or symptoms. Patients may present with subtle signs of weight gain and an inability to fit into clothes. Physical examination reveals shifting dullness to percussion (1.5 L of ascitic fluid), fluid waves (10 L), and bulging flanks.²⁶³ With progression of disease and massive ascites, respiratory status may be compromised secondary to increased intra-abdominal pressure and pleural effusions, which are often present and usually located on the right side. The progression may be slow or more rapid after an inciting event, such as a variceal bleed or infection.

Stigmata of poor liver function include peripheral muscle wasting, palmar erythema, spider angiomas, peripheral edema, a palpable liver, and caput medusae (dilated periumbilical veins). With progressive ascites and increased abdominal pressure, umbilical and inguinal hernias often develop and may be difficult to manage. Abdominal distention may be caused by gastrointestinal gas rather than ascites. Gas can be differentiated from fluid by eliciting hyperresonance to percussion, secondary to gas, as opposed to dullness with fluid. The most widely used test for the diagnosis of ascites is ultrasonography, which

can also be helpful in determining the best location for therapeutic and diagnostic paracentesis.

Diagnostic Paracentesis. The differential diagnosis of ascites is presented in [Table 59-12](#). Determination of the character of the ascitic fluid is helpful in establishing the diagnosis. Paracentesis may be performed in the midline, midway between the umbilicus and the pubic symphysis. The fluid from patients with cirrhosis is usually straw colored and clear; measurements of protein (usually <2 g/dL), quantitative cell counts, and microbiologic culture and determination of pH, amylase, glucose, and albumin levels should be obtained. The serum-to-ascitic fluid albumin gradient (SAG) is calculated by subtracting the albumin concentration in ascites from the level found in serum. This gradient is helpful in determining the cause of ascites; high values (>1.1 g/dL) are generally associated with portal hypertension, whereas lower levels may be associated with other disorders, including malignancy.²⁶⁴

Treatment. Initial therapy is usually directed at control of renal sodium and water retention, with bed rest and dietary manipulation. The upright position exacerbates sodium retention as a result of venous pooling and relative hypovolemia. Up to 15% of patients respond to this therapy alone with a natriuresis. A low-sodium diet is a critical part of the management of patients with cirrhosis (1 to 2 g of sodium per day or 45 to 90 mEq/d). A major problem with a strict low-sodium diet is lack of palatability and poor compliance. Fluid restriction is also an essential component of therapy in patients in whom hyponatremia develops (sodium concentration <125 mEq/L), with only 1,000 to 1,500 mL of fluid allowed each day.

For the 85% to 95% of patients who do not respond to bed rest and fluid and salt restriction, the mainstay of treatment is diuresis ([Table 59-13](#)). The loop diuretic furosemide and the potassium-sparing diuretic spironolactone are the two most widely used agents, and they can be combined to minimize side effects and maximize effectiveness. A ratio of 40-mg furosemide to 100-mg spironolactone generally maintains potassium homeostasis. A diuresis of approximately 500 mL/d is the goal for patients with mild ascites and of up to 1 to 2 L/d for patients with both ascites and peripheral edema. More than 90% of patients respond to the combination of dietary manipulation and diuretics.^{263,265}

Complications of the use of spironolactone include painful breast enlargement in males, hyperkalemia, and metabolic acidosis. Complications of the more potent furosemide include prerenal azotemia, which occurs in approximately 20% of patients as a result of excessive diuresis and hypovolemia.²⁷⁴ Additional complications include hyponatremia and encephalopathy.

Large-volume paracentesis (removal of 4 to 6 L of ascitic fluid per day) and total paracentesis are techniques that can be used for patients with large amounts of fluid who are experiencing symptoms and are not responding to the aforementioned therapeutic endeavors. Patients requiring paracentesis usually have severe underlying liver disease and a 1-year survival rate of 25%.²⁶⁶ The technique of paracentesis involves placing a catheter into the abdominal cavity, either in the lower midline or in one of the lower quadrants. Care is taken to enter lateral to the rectus muscle and avoid the inferior epigastric artery. More than 30 L of fluid can be removed by means of total paracentesis, with 6 to 10 g of albumin infused intravenously for each liter of ascitic fluid removed.^{263,265,266} The albumin commonly is administered in the form of 25% albumin (12.5 g/50 mL). Controversy exists regarding the need for albumin replacement therapy in patients undergoing total paracentesis and repetitive large-volume paracentesis. Patients who have less than 5 L of ascitic fluid removed do not require albumin replacement.²⁶⁷

TREATMENT

Table 59-13 Treatment of Ascites

Bed rest
Sodium restriction 1–2 g/d (45–90 mEq/d)
Fluid restriction 1–1.5 L/d
Diuretics
Spironolactone 50 mg PO q8h Maximum of 100 mg q6h
Furosemide 40–370 mg/d
Antibiotics
Cefotaxime 2 g IV q12h
Ofloxacin 400 mg PO q12h
Prophylaxis
Norfloxacin 400 mg/d while hospitalized
Ciprofloxacin 750 mg PO weekly
Norfloxacin 400 mg/d for 6 mo
Trimethoprim/sulfamethoxazole One double-strength tablet five times a week

The efficacy of paracentesis in the treatment of tense ascites has been studied extensively. Repetitive large-volume paracentesis has been shown to be as effective as diuretics in the treatment of moderate to severe ascites, with fewer systemic complications. A decreased length of hospital stay with no increase in the incidence of spontaneous bacterial peritonitis has been noted.²⁶⁸ Paracentesis has become the therapy of choice for severe ascites.

Peritoneovenous shunts are surgically placed tubes that connect the peritoneal cavity with the superior vena cava via the internal jugular vein (Fig. 59-16). The two main types are the LeVeen shunt and the Denver shunt, both of which have a one-way valve that allows unidirectional movement of ascitic fluid from the peritoneal cavity into the systemic circulation. Although these shunts are effective in decreasing the volume of ascitic fluid, a significant number of major complications have been noted, including disseminated intravascular coagulation, heart failure, and sepsis,^{266,269} and associated mortality rates are high (approximately 20%).²⁷⁰ The shunt is occluded in approximately 50% of patients at 1 year, and no improvement in survival is noted.²⁶⁶ The use of these shunts has drastically decreased with the development of the TIPS procedure. In addition to the use of TIPS, the placement of peritoneovenous shunts is now done percutaneously, further increasing the safety of these procedures.

Surgically created portosystemic shunts have been used in the past for the treatment of ascites. Because of high morbidity and mortality rates, an increase in encephalopathy and progression to liver failure, and the addition of the TIPS procedure to treatment options, surgically created shunts are now used infrequently for this indication alone. As discussed earlier, the TIPS is a total nonselective shunt that decompresses the portal system and reduces pressure at the hepatic sinusoids, thereby eliminating the drive for the production of ascitic fluid. In a study evaluating the use of TIPS for the treatment of medically refractory ascites, the ascites resolved completely in almost 75% of patients, and a partial response was noted in an additional 20%.²⁷¹ In addition, renal function improved during the 6 months of follow-up. TIPS in this group of patients, however, was associated with an increase in the number of cases of encephalopathy. Although survival appears to be unaffected by a TIPS procedure when compared with large-volume paracentesis, TIPS may simplify the management of the patient while on the transplant waiting list.

Figure 59-16. LeVeen peritoneovenous shunt used for routing ascitic fluid into the systemic circulation. The shunt consists of fenestrated tubing for insertion into the peritoneal cavity, a one-way valve, and a length of venous tubing for insertion into the superior vena cava.

12 Spontaneous bacterial peritonitis is a potentially lethal complication of portal hypertension with ascites that occurs in up to 10% of patients. The cause of spontaneous bacterial peritonitis is unknown. Antecedent gastrointestinal hemorrhage is common, and spontaneous bacterial peritonitis in this setting may be related to bacterial translocation from the gut. Deficits in immune function, both systemically and within the abdomen, including depressed²⁷² reticuloendothelial function,^{273–275} low ascitic protein concentration, and deficient ascitic opsonic activity, may play a role. Patients often present with abdominal pain and fever, but 10% to 20% of cases are discovered on routine paracentesis.^{276–278} In addition, patients may present with other signs not clearly related to spontaneous bacterial peritonitis, including worsening encephalopathy and deteriorating renal function. The diagnosis is easily made by examination of the ascitic fluid obtained by paracentesis. An elevated number of white blood cells ($> 250/\text{mm}^3$) are diagnostic. The vast majority of cases of spontaneous bacterial peritonitis are caused by a single organism, most commonly gram-negative enteric bacteria. Hematogenous spread may lead to infection with *Streptococcus pneumoniae* (Table 59-14). If more than one organism is present, the diagnosis of spontaneous bacterial peritonitis must be questioned, and a search for intra-abdominal disease (secondary peritonitis), such as a perforated viscus or diverticulitis, should be performed.

Table 59-14 Bacteriology of Spontaneous Bacterial Peritonitis

Organisms	Percentage of Total
<i>Escherichia coli</i>	40
Pneumococci	15
Streptococci	14
<i>Klebsiella</i>	7
<i>Pseudomonas</i>	3
<i>Proteus</i>	3
Staphylococci	3
Anaerobes	5
Other	20
Multiple isolates	10

Adapted from Targan S, Chow A, Gluze L. Role of anaerobic bacteria in spontaneous peritonitis of cirrhosis. *Am J Med* 1977;62:397.

The treatment of spontaneous bacterial peritonitis consists of supportive care and broad-spectrum antibiotics, most commonly cefotaxime, a third-generation cephalosporin. Protein replacement has been shown to significantly reduce mortality in patients with spontaneous bacterial peritonitis and is complementary to other interventions as established in the landmark publication from Barcelona.²⁷⁹ Other antibiotics with proven efficacy include ofloxacin, a quinolone. This antibiotic has potent activity against gram-negative organisms and reaches high levels in ascitic fluid. For patients who are clinically stable and able to take oral medications, this is the drug of choice. Cure can be achieved in 75% to 90% of cases, but mortality rates are high, ranging from 20% to 40%.^{280,281} The poor prognosis associated with spontaneous bacterial peritonitis warrants consideration of liver transplantation.

Prophylactic oral or intravenous antibiotics are indicated for three distinct groups of patients with cirrhosis with ascites: (a) those with gastrointestinal hemorrhage, (b) those with low protein counts in the ascitic fluid (<10 to 15 g/L), and (c) those who have survived an episode of SBP.^{282,283} The preferred antibiotics used in patients with hemorrhage are 7 days of either intravenous ceftriaxone or oral norfloxacin.²⁸³ These antibiotics reduce the incidence of spontaneous bacterial peritonitis from approximately 15% to 20% to 3% to 9% and cause few side effects.^{284–286} A meta-analysis evaluating the use of prophylactic antibiotics in patients with gastrointestinal hemorrhage confirmed the utility of prophylaxis, with an approximately 30% decrease in the incidence of infection, a 20% decrease in the incidence of spontaneous bacterial peritonitis and bacteremia, and a 10% improvement in overall survival.²⁸⁷ In patients with low protein levels in the ascitic fluid, multiple regimens have proved effective in reducing the incidence of spontaneous bacterial peritonitis, from approximately 20% to less than 5%.^{287–289}

Hernias and Ascites

Hernias of the anterior abdominal wall occur in up to 20% of patients with cirrhosis. The causes include increased intra-abdominal pressure and nutritional deficits, with muscular wasting and thinning of the fascia. If the hernias are left untreated, complications include incarceration, rupture, strangulation, and leakage. Patients with hernias and decompensated cirrhosis need to be evaluated for liver transplantation. In patients with stable liver function, hernias should be treated electively, with preoperative paracentesis to decrease intra-abdominal pressure. No increase in complication rates was noted in a study comparing the outcome of umbilical hernia repair in patients with and without ascites. A longer hospital stay and a significantly higher recurrence rate (73% vs. 14%) were noted, however, in the group of patients with ascites.^{290–292} We favor the use of abdominal drains to remove the ascites until the incision is healed, thereby preventing ascites from leaking through the wound. Meticulous fluid management is essential during the postoperative period to prevent early reaccumulation of ascites.

In patients with severe ascites, TIPS should be performed before hernia repair to ensure a good result. Emergency repair of hernias complicated by skin breakdown with ascites leak or incarceration or strangulation is managed in a similar fashion with preoperative large-volume paracentesis, and aggressive control of ascites postoperatively.

Chapter 60

Hepatic Neoplasms

Junichi Shindoh and Jean-Nicolas Vauthey

Key Points

- 1 Given the increasing complexity in the field of liver surgery, the surgical indications for hepatic neoplasms should be determined by a multidisciplinary team, including hepatobiliary surgeons, to optimize the treatment approach and adequate timing of surgery for patients who would benefit from hepatic resection.
 - 2 Child–Turcotte–Pugh (CTP) classification describes the overall status of the hepatic functional reserve and the risk of treatment. Surgical resection is generally indicated for CTP class A or highly selected CTP class B patients, whereas CTP class C is a contraindication for hepatic resection.
 - 3 Surgical therapy of benign hepatic neoplasms should be confined to symptomatic patients or those with a risk of malignant transformation (e.g., biliary cystadenoma, hepatic adenoma [HA]).
 - 4 The choice of therapy for HCC should be individualized based on the tumor burden, degree of underlying liver disease, patient performance status, and overall possibility of side effects or complications balanced with acceptable clinical results.
 - 5 Complete resection of colorectal liver metastases (CLM) is associated with an improved 5-year survival rate of up to 58%. Adequate assessment and preoperative management are essential in selecting patients with resectable or potentially resectable CLM.
 - 6 For surgical planning, precise anatomic interpretation of the intrahepatic vascular structures is needed. Three-dimensional liver simulation techniques have recently been introduced which enable easy access to anatomic information and help with adequate surgical planning.
 - 7 Portal vein embolization (PVE) is a safe and minimally invasive procedure to increase the size of the future liver remnant (FLR) and decrease the surgical risk of extended hepatectomies. Failure to respond to PVE is associated with postoperative hepatic insufficiency and mortality due to liver failure.
 - 8 Adequate exposure of the surgical field and control of bleeding during hepatic parenchymal transection are basic requirements for safe liver surgery. Liver surgeons should be familiar with techniques for safe handling of the liver.
 - 9 Laparoscopic liver resection has been recognized as a feasible and safe procedure for selected patients undergoing minor resections, and this approach has recently been expanded to major hepatectomies. The indication for the laparoscopic approach should be determined by considering the technical feasibility, the surgeon's surgical skill, and the oncologic curability of the procedure.
-

INTRODUCTION

The management of hepatic neoplasms is an increasingly complex and multidisciplinary area of surgery. With advances in surgical technique and perioperative care, the safety of liver resection has dramatically improved over the decades and the mortality rate after major hepatectomy has recently been reported to be < 5% at high-volume hepatobiliary centers.^{1,2}

Liver resection and liver transplantation are widely accepted as curative surgical options for selected hepatic neoplasms. Surgical treatment for hepatic neoplasms requires the balancing of two conflicting factors, oncologic curability and surgical safety. The size of the future liver remnant (FLR) affects mortality and morbidity after liver resection, and the chance of cure is often linked to the extent of resection.^{3,4} Therefore, the surgical indication should be determined based on the balance of surgical curability and extent of liver resection, especially for patients who have impaired hepatic functional due to underlying chronic liver disease. In this chapter, we review the basic principles of surgical management and appropriate surgical techniques for hepatic neoplasms.

PRIMARY ASSESSMENTS FOR TREATMENT SELECTION

Overview

When a hepatic neoplasm is found, the initial diagnostic steps should include (1) precise anatomic description of the hepatic lesion (size, number, location, and relation to intrahepatic vascular structures), (2) evaluation of the hepatic functional reserve in the underlying liver, and (3) assessment of the oncologic feature of the lesion in question.

The initial treatment is selected based on the information obtained from these primary assessments. When surgical management is considered, further workup is needed to determine or optimize the surgical indication through (1) detailed anatomic assessment and (2) systematic volumetry of FLR to stratify the risk of postoperative hepatic insufficiency and mortality from liver failure. If the estimated FLR is too small according to the hepatic functional reserve of an individual patient, portal vein embolization (PVE) or a two-stage approach^{5,6} is considered in combination with local or systemic therapy, as appropriate.

1 Given the increasing complexity in this field of surgery, the surgical indication should be determined by a multidisciplinary team, including hepatobiliary surgeons. In the era of effective chemotherapy and various radiologic interventions, the surgical indication can change during the initial nonsurgical treatment even in patients with initially unresectable hepatic lesions. Because only surgical resection offers a chance of cure for patients with advanced hepatic malignancies, a multidisciplinary approach is important to identify patients who would benefit from surgery and to optimize overall treatment outcomes.

Screening for Underlying Liver Disease

Assessment of a patient with a new diagnosis of a hepatic neoplasm should begin with consideration of any underlying chronic liver disease. Viral hepatitis is the most common cause of chronic liver disease and primary liver cancer, affecting 240 million people with hepatitis B (HCB) and 130 to 150 million people with hepatitis C (HCV) worldwide – most of whom are unaware of their disease.⁷ Thus, routine screening of viral hepatitis is mandatory for patients with hepatic neoplasms. The number of serology-negative patients with primary liver cancers is increasing, and alcoholic liver disease and nonalcoholic liver disease are the next leading causes of chronic liver disease. Both are characterized by histologic alterations, including steatosis, and each can lead to cirrhosis and primary liver cancer.^{8,9} Careful history taking is important primarily to specify the risk of fatty liver disease, such as those due to obesity, alcohol abuse, diabetes mellitus, and metabolic syndrome. In addition, cholestatic liver disease is an important etiology for chronic liver disease because it is a common cause of decompensated cirrhosis requiring liver transplantation. Primary sclerosing cholangitis is a strong risk factor for cholangiocarcinoma and cases of end-stage primary sclerosing cholangitis are frequently complicated with malignant biliary stricture, which may be difficult to distinguish from benign biliary strictures. Finally, a history of systemic therapy for hepatic malignancy is an increasingly important factor in the era of effective chemotherapy. Several studies have confirmed that prolonged systemic therapy is associated with regimen-specific histopathologic injury of the liver¹⁰⁻¹² and decreased hepatic functional reserve.¹²⁻¹⁵ Therefore, risk assessment of chemotherapy-induced liver injury is also necessary, especially for patients with colorectal liver metastases (CLM) for whom systemic treatment has been used.

Laboratory Tests

A comprehensive metabolic panel, a complete blood count, and measurement of coagulation parameters are essential for potential candidates for surgery. The basic functional status of the liver can be evaluated by serum albumin concentration, bilirubin concentration, and transaminase level. The renal function is also important because advanced liver disease is frequently compromised with renal dysfunction and impaired renal function is correlated with poor prognosis. Regarding the complete blood count, attention should be paid to platelet count. Thrombocytopenia is reportedly correlated with the degree of fibrosis in the underlying liver, and thrombocytopenia suggests the presence of hypersplenism and portal hypertension, which are associated with increased need for treatment. Among the coagulation parameters, prothrombin time is the most sensitive indicator of synthetic function of the liver. Because prothrombin time represents the activity of rapid-turnover proteins synthesized exclusively in the liver, prolonged prothrombin time indicates functional impairment of the liver in a real-time fashion.

Measurement of tumor markers specific to hepatic malignancies helps the diagnostic process for hepatic neoplasms. For hepatocellular carcinoma (HCC), serum alpha-fetoprotein (AFP) level, proportion of Lens-culinaris agglutinin-reactive fraction of AFP, and plasma des-gamma-carboxyprothrombin (DCP) level have been reported to be useful for both diagnosing and predicting surgical outcomes.¹⁶ Recent studies have reported that these markers are also predictive for posttransplant recurrence of HCC.^{17–19} For the other hepatic neoplasms, serum levels of carcinoembryonic antigen and CA19-9 are usually screened to evaluate the malignant potential of the lesions.

Stratification of Overall Status of the Hepatic Functional Reserve

2 For selection of treatment, the overall status of the hepatic functional reserve and the risk of treatment are stratified by the Child–Turcotte–Pugh (CTP) score, which is calculated using the presence of encephalopathy, presence of ascites, serum bilirubin concentration, serum albumin concentration, and prothrombin time (Table 60-1). The CTP score is now included in various treatment algorithms for hepatic neoplasms,^{20–22} and liver resection is usually indicated for CTP class A patients or highly selected patients classified as CTP class B. The consensus is that CTP class C patients should not undergo surgical resection due to a high perioperative mortality rate.²¹ In the field of liver transplantation, the Model for End-Stage Liver Disease (MELD) score has recently been used as a more sensitive parameter for transplant allocation because of its accuracy in predicting patient mortality on waiting lists.^{23,24} Although its suitability and application for liver resection remains debatable,^{25,26} the MELD score reportedly predicts posttransplant outcomes through optimizing transplant allocation.^{27,28}

Table 60-1 Child–Turcotte–Pugh (CTP) Classification

	Points		
	1	2	3
Albumin (g/dL)	>3.5	2.8–3.5	<2.8
Bilirubin (mg/dL)	<2.0	2.0–3.0	>3.0
Prothrombin time			
Seconds	<4	4–6	>6
International normalized ratio (INR)	<1.7	1.7–2.3	>2.3
Ascites	None	Mild	Moderate to Severe
Encephalopathy	None	Grades I–II	Grades III–VI
CTP class A	5–6 points		
CTP class B	7–9 points		
CTP class C	10–15 points		

Imaging Studies

Adequate imaging is essential for diagnosis, staging, treatment planning, and evaluation of the response to chemotherapy of hepatic neoplasms. Computed tomography (CT) and magnetic resonance imaging (MRI) are the most common modalities used for diagnosing and evaluating patients with liver lesions. CT plays a central role in characterizing hepatic neoplasms because of its accessibility, practicality, low cost, and acceptable sensitivity and specificity. For diagnosis and adequate evaluation of tumor burden, dynamic contrast enhancement with a liver-specific protocol is necessary to characterize the vascularity and extension of the tumor. MRI combining gadolinium ethoxybenzyl diethylenetriamine pentaacetic acid (Gd-EOB-DTPA) delayed imaging and diffusion-weighted imaging provides the best performance for detecting and characterizing liver lesions, particularly those <10 mm in size.²⁹ Ultrasound is another important modality that is used both for preoperative diagnosis and postoperative follow-up. Although its sensitivity is inferior to CT and MRI, the advantages of ultrasound are that it is accessible and less invasive than the other diagnostic modalities. Contrast-enhanced ultrasound using the second-generation contrast medium perflubutane (Sonazoid) enables evaluation of vascularity and clear visualization of malignant lesions as areas lacking Kupffer cells. Furthermore, intraoperative application of this agent improves the diagnostic value of ultrasound and the curability of surgery.^{30,31} ¹⁸F-fluorodeoxyglucose positron emission topography (¹⁸F-FDG-PET) may be a powerful adjunct to other liver imaging techniques in selected patients. Niekel et al.³² reviewed 39 articles (3,391 patients) and showed that the estimated sensitivities to detecting CLM on a per-lesion basis for CT, MRI, and ¹⁸F-FDG-PET were 74.4%, 80.3%, and 81.4%, respectively. In addition, the usefulness of ¹⁸F-FDG-PET has been reported especially for detecting extrahepatic metastases or local recurrence.^{33,34} However, increased

sensitivity is usually associated with reduced specificity. Limitations of ^{18}F -FDG-PET include its limited availability, high cost, limited access to specialized techniques, and lack of expertise to interpret the results. Therefore, from a practical clinical perspective, CT, MRI, or both should be the first-line modalities for characterizing hepatic lesions and ^{18}F -FDG-PET can be used as the second-line modality for evaluating the metabolic features of the lesion or the presence of extrahepatic disease. Ultrasound should be used as a routine diagnostic tool throughout the perioperative period. It is mandatory for hepatobiliary surgeons to acquire expertise in ultrasonography.

Figure 60-1. Couinaud segmental anatomy of the liver. In Couinaud theory, the liver is divided in to two hemilivers, four sectors, and eight segments according to the portal venous ramification pattern. Three major hepatic veins represent the position of intersectoral plane (called scissura). LHV, left hepatic vein; MHV, middle hepatic vein; RHV, right hepatic vein.

Figure 60-2. Three-dimensional shape of the intersegmental plane. **Top left:** Lateral view of the right hemiliver. The right lateral sector indicated by the dark-gray color and an interdigitated demarcation line is visible on the liver surface (*white dotted line*). Segment VIII (S8) protrudes dorsolaterally (*arrows*) relative to Segment V (S5). **Top right:** Dorsolateral view of the cut surface after a simulated right lateral sectorectomy. The right scissure exhibits a concave shape because of the protrusion of Segment VIII (H, head; L, left; P, posterior). Axial computed tomographic image (**bottom left**) and diagram (**bottom right**) illustrating that the intersegmental border between Segments VIII and VII is not compatible with the plane of the right hepatic vein. The posterolateral part of the right hepatic vein in Segment VIII is presented. (Adapted from Shindoh J, Mise Y, Satou S, et al. The intersegmental plane of the liver is not always flat—tricks for anatomical liver resection. *Ann Surg* 2010;251(5):917–922.)

In radiographic evaluation, the tumor location is described according to Couinaud anatomy for liver segments.³⁵ In Couinaud theory, the liver can be divided into two hemilivers, four sectors, and eight segments defined as the territories of the first-, second-, and third-order portal branches, respectively (Fig. 60-1). Because typical systematic surgical resection follows the segmental anatomy of the liver, the location of tumor should be defined based on accurate understanding of the segmental anatomy of the liver. “Segment” is defined as a territory of a portal branch and its actual three-dimensional shape is not simple, despite depictions in many surgical textbooks.³⁶ For example, Segment VIII usually protrudes craniolaterally, overhanging the right hepatic vein (Fig. 60-2). Accordingly, a hepatic lesion located just to the cranial side or posterolateral side of the right hepatic vein is a Segment VIII tumor, which can be easily confirmed by tracking the nearest portal branches on CT images.

BENIGN HEPATIC NEOPLASMS

Cystic Lesions

Simple Cyst

The distinction between solid and cystic lesions is clinically important, as the vast majority of cystic lesions of the liver are benign in behavior. The majority of the incidentally diagnosed cystic lesions are simple cysts, which have no malignant potential and rarely become symptomatic. However, surgical treatment is considered for symptomatic giant cysts stretching the liver capsule or compressing the adjacent organs. Laparoscopic unroofing (Fig. 60-3) may be the ideal approach for these lesions, which has acceptably good outcomes and a negligible recurrence rate in experienced hands.³⁷

Figure 60-3. A huge hepatic cyst observed in the right hemiliver (**left**). Laparoscopic unroofing (**right**) was performed for this patient to relieve the abdominal pain associated with distension of the liver capsule. Cystic fluid was first suctioned and then the anterior wall of the cyst (*) was resected with an energy device. (Images courtesy to Dr. Yasuji Seyama.)

Polycystic Liver Disease

Polycystic liver disease (PLD) is a rare presentation of cystic liver lesions and can be difficult to manage.³⁸ Approximately 80% to 90% of PLD cases represent an autosomal dominant disease associated with polycystic kidney disease. In these patients, renal failure frequently occurs due to destruction of the kidney by multiple cysts. Although patients with PLD rarely develop hepatic failure regardless of the marked change in the distorted liver on imaging studies (**Fig. 60-4**), various symptoms caused by distention of the liver, stretching of the diaphragm, or compression of the adjacent organs require therapeutic intervention. Treatment for PLD should be performed in a stepwise fashion. Ultrasonically guided puncture of the cysts should be the first choice to decompress the distended cysts and drain the fluid. If percutaneous aspiration is not effective, the next option is laparoscopic fenestration of the cysts. Liver resection or transplantation should be the final treatment option. A limited number of patients require liver transplantation due to the progressive destruction of liver parenchyma and hepatic dysfunction. However, liver transplantation for PLD is a challenging procedure due to severe adhesion and huge liver size, usually causes major bleeding, and requires a large amount of transfusions especially for patients with a history of multiple interventions or surgery for PLD. A recent report suggested that a history of open intervention is a strong risk factor for severe postoperative complications, longer hospital stay, and poor long-term outcomes after transplantation.³⁹ Therefore, a minimally invasive approach is preferable for disease-directed interventions for PLD as long as this approach is viable.

Figure 60-4. CT image of a patient with polycystic liver associated with autosomal dominant polycystic kidney disease. The liver is markedly distended due to destruction of the liver by multiple cysts and compensatory regeneration of hepatic parenchyma. However, the hepatic function is maintained with an albumin level of 2.8 g/dL, bilirubin level of 1.5 mg/dL, and INR of 1.12, with slight ascites and no evidence of encephalopathy (Child–Turcotte–Pugh class B).

Biliary Cystadenoma

3 Most hepatic cysts are asymptomatic, and surgical resection is indicated only for lesions for which there is concern for malignancy or malignant potential. Wall enhancement in contrast-enhanced CT, serrated or septated wall visualized by ultrasound, or rapid increase in size suggests malignant potential of a lesion. Biliary cystadenoma is the common cystic lesion with malignant potential, accounting for 5% of all cystic lesions in the liver.⁴⁰ These lesions arise from the biliary epithelium and typically present in middle-aged women. Because it is difficult to distinguish between cystadenoma and cystadenocarcinoma (Fig. 60-5) and because cystadenoma has a propensity toward local recurrence and malignant degeneration to cystadenocarcinoma,^{41,42} surgical resection is indicated primarily when biliary cystadenoma is suspected.

Solid Lesions

Solid lesions should be handled with care because benign lesions are sometimes difficult to discriminate from malignant tumors.

Figure 60-5. CT image of a cystadenocarcinoma. A multicystic lesion with an enhanced intracystic papillary component was observed (arrow).

Hemangioma

Hemangioma is the most common benign lesion observed in the liver; the estimated prevalence is 3% to 20%.⁴³ Most hemangiomas are identified in individuals aged 40 to 60 years and appear to be more common in women, with a female-to-male ratio of 2:1.⁴⁴ Grossly, hemangiomas are well-circumscribed and compressible lesions. Histopathologically, multiple blood vessels lined by endothelial cells are present.⁴⁵ The majority of hemangiomas are small asymptomatic lesions that can be managed nonsurgically. Spontaneous or traumatic rupture of hemangioma in exceptional cases has been reported, but the risk of rupture is considered very low. Therefore, the majority of these cases can be left untreated with regular follow-up imaging studies.

Accurate radiographic diagnosis of a hepatic hemangioma is important, as establishment of this diagnosis requires no additional intervention for the majority of patients. For diagnosis, a dynamic study is the most important for characterizing the hemodynamics in a lesion. Contrast-enhanced CT demonstrates a typical pattern of nodular enhancement from the periphery with central filling on delayed images (Fig. 60-6). Contrast-enhanced MRI also shows similar patterns in dynamic studies, and a very high intensity in T2-weighted images is suggestive of hemangioma. A diagnosis of hemangioma should be made based on these radiographic findings. Although biopsy is not absolutely contraindicated, a fatality from uncontrollable bleeding has been reported, so unnecessary biopsy should be avoided.⁴⁶

Surgical resection is warranted in the setting of abdominal symptoms,^{47–49} spontaneous rupture,⁵⁰ rapid growth of the lesion,⁵¹ or coagulopathy due to Kasabach–Merritt syndrome. Elective surgical treatment is accomplished by either enucleation or formal hepatic resection. Enucleation is often easily performed because hemangiomas are exophytic to some degree and a pseudocapsular plane can be developed efficiently. Hemangiomas typically have limited outflow and the internal pressure may be high. Early ligation of the feeding arteries, especially in patients with large hemangiomas, is a key point, as the size reduction caused by the decompression is technically beneficial for surgical manipulation and resection.

Focal Nodular Hyperplasia

Focal nodular hyperplasia (FNH) is the second most common benign neoplasm of the liver. A clinical

and autopsy series estimated that FNH occurs in 4% to 8% of individuals, with a strong predilection for women aged 20 to 50 years.⁴³ Unlike the origin of hemangioma or hepatocellular adenoma, the origin of FNH is thought to be due to hyperplastic growth of normal hepatocytes with a malformed biliary draining system or a hyperplastic response to a pre-existing arteriovenous malformation. FNH does not contain a portal venous supply.

Figure 60-6. Nodular enhancement typically observed in hemangioma in dynamic CT. The mass is gradually enhanced from the peripheral part to the central part of the lesion.

Figure 60-7. Typical dynamic CT image of focal nodular hyperplasia. The lesion is homogeneously enhanced in the arterial phase with central hypodensity area suggestive of a central scar (**left**). The mass becomes isodense in the portal phase (**right**).

In plain CT, the lesion is isoattenuated with normal liver and may exhibit the characteristic hypoattenuated central scar. With contrast in the arterial phase, FNHs enhance brightly and become again isoattenuated to adjacent parenchyma in the portal phase ([Fig. 60-7](#)). The central scar may enhance on delayed phases. MRI reveals a similar dynamic enhancement pattern: FNHs appear isointense on T1-weighted images and hyperintense on T2-weighted sequences. With gadolinium enhancement, the lesion is homogeneously enhanced in the arterial phase and the central scar becomes hypointense in the delayed phase.

The majority of FNHs is asymptomatic and found incidentally on abdominal imaging for other indications. Because of the benign nature of FNHs and the very low risk of spontaneous rupture, treatment should be reserved for patients with persistent symptoms not explained by another problem.

Hepatic Adenoma

Hepatic adenoma (HA) is a rare benign tumor with an estimated prevalence of approximately 1% on postmortem examinations.⁵² Typically, HAs occur in women of child-bearing age who often have a history of long-term use of oral contraceptives. In the majority of the cases, HA lesions are solitary and asymptomatic. However, the presence of multiple nodules (typically >10 nodules) indicates a distinct entity called hepatic adenomatosis, which has a different implication for treatment.⁵³

Adenomas are well-circumscribed lesions that contain sheets of hepatocytes without intervening biliary ductules or portal tracts. Conventionally, HA was considered to have variable imaging characteristics and was described as a heterogeneous hypervascular mass with areas of fat, hemorrhage, and necrosis on multiphase CT or MRI.⁵⁴ With the introduction of the new phenotype–genotype classification of HA, however, correlation between the imaging characteristics and different subtypes has been reported.^{55,56} HAs are grouped into 1 of 4 subtypes. HA-H (*HNF1A*-mutated hepatic adenoma) is the most frequently occurring one (35% to 40%), presenting steatosis and absence of inflammatory infiltrate or cytologic atypia. This subtype is frequently associated with somatic mutation of the *TCF1* (*HNF1A*) gene or heterozygous germline mutations of the *CYP1B1* gene. HA-B (β -catenin–mutated hepatic adenoma, 15% to 19%) is morphologically characterized by pseudoacinar formation and mild cytologic atypia. Steatosis is rare and inflammation is absent in this subtype. β -Catenin gene-activating mutations are frequently observed in this subtype. HA-I (inflammatory hepatic adenoma, 30% to 35%) exhibits pseudoportal tracts that lack veins and bile ducts and contain large, thick-walled arteries surrounded by fibroconnective tissue with variable ductular reaction and inflammation. The last subtype, HA-U (10%), is associated with gain-of-function mutations of the *IL6ST* gene. These HAs lack distinctive morphologic and molecular features.

Patients with HAs appear to have a risk of either rupture or malignant transformation (estimated risk of 4.2% to 4.5%^{57,58}), which is different from the other benign lesions. The HA-B subtype has been found to be more frequently associated with the development of HCC.^{59,60} For small lesions (<5 cm), some experts have recommended withdrawal of oral contraceptives in the expectation of tumor regression.^{61,62} However, regression of HA upon cessation of oral contraceptives does not remove the risk of malignant transformation in women.⁶³ High-risk groups for malignant transformation include male patients, patients with a history of androgenic or anabolic steroid intake, and patients with glycogen storage disease.

The potential for malignant transformation and the risk of hemorrhage drive active surgical interventions for large HAs. Surgical resection is recommended for HAs >5 cm, those with intratumoral hemorrhage, and those that increase in size.^{64–67} HAs are hypervascular tumors and are sometimes difficult to distinguish from HCC. Typically, HAs are represented by bright enhancement in the arterial phase and iso- to hypodensity in the portal phase (Fig. 60-8). With MRI, HAs are visualized as well-defined lesions with isointense or hyperintense features on T1- and T2-weighted images, depending on the fat content. Similar to dynamic CT, gadolinium enhancement shows marked enhancement in the arterial phase and isointensity in the portal phase.

PRIMARY HEPATIC MALIGNANCIES

Hepatocellular Carcinoma

Primary liver cancer is one of the most common solid tumors and the second-leading cause of cancer-related deaths worldwide.⁶⁸ Despite recent developments in preventing and treating viral hepatitis, nearly 750,000 deaths were reported in 2012 for patients with primary liver cancer. Among these cases, HCC is the most common type of hepatic malignancy. There is wide geographic variability in incidence, with the majority of the cases occurring in developing countries compared with developed countries. China alone accounts for more than half of the new cases of liver cancer; other high-incidence areas are sub-Saharan Africa, Japan, and Southeast Asia, where viral hepatitis or aflatoxin exposure is more endemic. In the United States, the incidence of HCC is increasing the second-fastest of all tumor types, probably due primarily to the HCV epidemic.⁶⁹ There is also global variation in the risk factors for HCC. HBV and HCV infections are the leading causes of HCC, accounting for 75% of the cases worldwide.⁷⁰ HBV infection is more common except in Japan, where HCV infection is the most common cause of HCC. Alcoholic liver disease accounts for a significant proportion of HCC in the Western countries. Aflatoxin exposure is also an important risk factor in China and sub-Saharan Africa.

Figure 60-8. A huge hepatic adenoma found in a 31-year-old woman. Dynamic CT revealed early enhancement in the arterial phase (**left**) and iso- to hypodensity in the portal phase (**right**). This patient had no underlying liver disease and both serum alpha-fetoprotein level and plasma des-gamma-carboxyprothrombin level were within normal limits.

Screening measures for HCC have been assessed in various studies, which primarily focus on the roles of serum AFP level and ultrasound. The American Association for the Study of Liver Disease (AASLD) has created guidelines regarding the use of these screening techniques based on the best existing evidence.²⁰ The AASLD currently recommends serial hepatic ultrasonography and serum AFP measurement every 6 to 12 months for at-risk populations (e.g., any patient with cirrhosis). Similarly, the Japanese Society of Hepatology has recommended hepatic ultrasonography and serum AFP or plasma DCP measurement every 3 to 4 months and dynamic CT or MRI every 6 to 12 months for very-high-risk populations (e.g., those with HBV- or HCV-related cirrhosis), and hepatic ultrasonography and assessment for tumor markers every 6 months for high-risk populations (e.g., HBV- or HCV-related chronic hepatitis, or cirrhosis with other etiologies) with or without dynamic CT or MRI every 6 to 12 months, as appropriate.⁷¹ A randomized controlled trial from China reported that the use of ultrasound and AFP enables early detection of HCC and lowers HCC-related mortality by 37% in patients with HBV infection.⁷² Various nonrandomized studies have confirmed prognostic improvement through regular surveillance programs among patients at high risk of HCC.^{73–75} Regarding the interval of screening, a recent meta-analysis revealed that surveillance every 6 months is significantly better than screening every 12 months for the early detection of HCC. Santi et al.⁷⁶ reported that 70% of newly diagnosed HCCs fell within the Milan criteria (solitary tumor ≤ 5 cm or ≤ 3 tumors with each tumor ≤ 3 cm)⁷⁷ when screening occurred at least every 6 months, while the proportion of HCCs that fell within the Milan criteria was 57% and the overall survival rate was inferior with surveillance every 6 to 12 months. When a suspected nodule is detected during regular screening, a contrast-enhanced three-phase CT or MRI is needed. Because HCCs are fed mainly by arterial flow, early enhancement and washout of contrast on the delayed phase of the scan are typical findings suggestive of HCC (**Fig. 60-9**). These enhancement characteristics increase the specificity of the scan to $> 95\%$.⁷⁸

4 The choice of therapy is individualized based on the tumor burden, degree of underlying liver disease, patient performance status, and overall possibility of side effects or complications balanced with acceptable results. The Barcelona Clinic Liver Cancer (BCLC) staging system⁷⁹ is widely used to stratify patients for specific therapies (**Algorithm 60-1**). However, the limitation of the BCLC algorithm is that it is fairly conservative with regard to the application of surgical therapy. Patients with larger solitary tumors are not considered surgical candidates despite growing experience with resection with acceptable outcomes in this group.^{80,81} In the guidelines on liver cancer treatment proposed by the Japan Society of Hepatology,²² surgical resection is indicated for CTP class A or class B patients with HCCs with up to three nodules irrespective of the size of each tumor, while liver transplantation is limited to CTP class C patients meeting the Milan criteria.

For HCC patients undergoing liver resection, strict assessment of the hepatic functional reserve is important because HCC usually develops in an injured liver and, accordingly, the maximum extent of resection must be estimated carefully. Functional investigations have been proposed to better evaluate the severity of chronic liver disease. Measurement of indocyanine green (ICG) retention rate at 15 minutes (ICG-R15) is the most frequently used test. For patients with obstructive jaundice or congenital intolerance to ICG, ^{99m}Tc-galactosyl human serum albumin (GSA) scintigraphy sensitively estimates the hepatic functional reserve. **Algorithm 60-2** shows a decision tree used for surgical planning according to

the individual hepatic functional reserve (Makuuchi criteria).⁸² By strictly following this algorithm, no mortality due to hepatic insufficiency was reported in the University of Tokyo series.¹

Figure 60-9. Typical enhancement pattern of HCC with early enhancement in the arterial phase (left) and washout in the portal phase (right).

Because HCC tends to spread via portal veins, anatomic resection of the tumor-bearing portal territory is a theoretically reasonable approach (Fig. 60-10). Although the efficacy of anatomic resection remains controversial, various studies have reported prognostic superiority of anatomic resection with an apparent lower local recurrence rate and a higher recurrence-free survival rate compared to nonanatomic limited resection of the liver.^{83–85} Liver transplantation is another surgical approach with a theoretically higher chance of eradicating the tumor burden, especially for patients with severe hepatic dysfunction. Clinical outcomes of liver transplantation for HCC were initially poor in the early era. However, after the landmark study by Mazzaferro et al.,⁷⁷ good survival outcomes are expected in select HCC patients with tumors of limited size and a small number of nodules (Milan criteria). The selection criterion for transplantation used by Mazzaferro et al.⁷⁷ was a tumor diameter of ≤ 5 cm in patients with a single HCC or ≤ 3 cm in patients with 2 or 3 lesions. This criterion has since been extended with or without tumor markers or biopsy findings in several high-volume transplant centers (Table 60-2).^{86–97}

Intrahepatic Cholangiocarcinoma

Intrahepatic cholangiocarcinoma (ICC) is a relatively uncommon disease, accounting for 5% to 30% of all primary liver malignancies.⁹⁸ In the United States, the age-adjusted incidence of ICC increased from 0.32 in 1975 to 0.85 per 100,000 population in 2000 and has yet to plateau.⁹⁹ The overall 5-year survival rate for patients with unresectable tumor is dismal: 5% to 10%. Because systemic therapy for ICC has not yet been established, surgical resection offers the only chance for cure. However, the overall 5-year survival rate after curative-intent surgery is disappointing at 20% to 35%.¹⁰⁰

Figure 60-10. Theoretical concept of anatomic resection for HCC. This schema shows an example of resection for HCC located in the ventral part of Segment VIII. The *dashed line A-A'* indicates nonanatomic limited resection with adequate surgical margin and the *dotted line B-B'* represents anatomic resection of the ventral part of Segment VIII. Because the “tumor-bearing” portal territory is at high risk of harboring micrometastases scattered via portal veins (*arrows*), systematic removal of the corresponding portal region would offer a better chance of eradicating the cancer cells. With systematic removal of the territory of the ventral branch of Segment VIII, the tumor-bearing portal territory, which is at high risk of micrometastases, can be resected. T, tumor; P8v, ventral branch of Segment VIII portal pedicle; P8d, dorsal branch of Segment VIII portal pedicle; MHV, middle hepatic vein; V8i, intermediate vein for Segment VIII.

ICC is thought to derive from a common hepatic progenitor cell that may also give rise to HCC,¹⁰¹ and combined hepatocellular-cholangiocarcinoma having histopathologic features of both HCC and ICC is sometimes observed. Risk factors for ICC have not yet been established, although chronic liver disease and cirrhosis are reportedly correlated with ICC. On dynamic imaging studies, ICC is not enhanced due to the hypovascular nature of this tumor type. However, various degrees of ring enhancement are observed surrounding the lesion, reflecting the fibrous connective tissue frequently observed around the tumor. In laboratory tests, elevated carcinoembryonic antigen or CA19-9 in primary solid liver lesion is suggestive of ICC.

A recent meta-analysis showed that factors associated with shorter overall survival included older patient age, larger tumor size, multiple tumors, lymph node metastasis, vascular invasion, and poor tumor differentiation. Because up to 30% of patients have lymph node metastases, routine lymphadenectomy is recommended,¹⁰² although the survival benefit remains controversial.

METASTATIC LIVER TUMORS

Colorectal Liver Metastases

5 Colorectal cancer is the second-leading cause of cancer-related deaths in the United States. About 20% to 25% of colorectal cancer patients are found to have synchronous CLM,^{103,104} and 35% to 55% develop CLM during the course of the disease.¹⁰⁵ The 5-year survival rate after curative resection of CLM has been reported to be up to 58%,¹⁰⁶⁻¹⁰⁸ while the median survival duration for patients with CLM without any treatment is approximately 6 months.¹⁰⁴ Therefore, adequate assessment and preoperative management are important in selecting patients with resectable or potentially resectable CLM who are candidates for liver resection.

CLMs are classified as stage IV colorectal cancer. However, with recent advancements in chemotherapy and surgical management, the resectability of CLM has dramatically increased and long-term survival after resection of CLM has significantly improved.¹⁰⁹ The practical keys to the initial management of CLM include precise assessment of the extension of disease and the proper selection of the initial therapeutic options. Although surgical resection is potentially the most curative strategy for CLM, a multidisciplinary approach by surgeons, medical oncologists, radiologists, and pathologists is essential for selecting the patients who would benefit from surgery and to determine the optimal timing of surgery ([Algorithm 60-3](#)).¹¹⁰

Table 60-2 Published Results of Expanded Liver Transplant Eligibility Criteria for Hepatocellular Carcinoma

Authors (Year)	Eligibility Criteria	Overall Survival Rate (%)					
		Within Milan Criteria			Within Extended Criteria		
		1 yr	3 yrs	5 yrs	1 yr	3 yrs	5 yrs
Yao et al. (2001) ⁽⁹⁶⁾	“UCSF criteria” No extrahepatic spread or macrovascular invasion Solitary tumor with diameter ≤6.5 cm, OR ≤3 nodules with maximum diameter ≤4.5 cm and total tumor diameter ≤8.0 cm	91	—	72	90	—	75

MVI, microvascular invasion; UCSF, University of California San Francisco; AFP, alpha-fetoprotein; DCP, des-gamma-carboxyprothrombin.
^aUpdated data with personal communication.

In imaging evaluation, the choice of imaging technique for pretreatment assessment of CLM depends on the local expertise and the availability of imaging modalities. However, at least CT of the chest, abdomen (including three-phase liver protocol CT), and pelvis should be performed routinely to evaluate patients with CLM, with selective use of MRI and PET to further evaluate small hepatic nodules or extrahepatic disease.

Algorithm 60-3. Multidisciplinary treatment approach for colorectal liver metastasis. (Adapted from Kopetz S, Vauthey JN. Perioperative chemotherapy for resectable hepatic metastases. *Lancet* 2008;371:964–965 with permission.)

The surgical indication for CLM should be considered from two standpoints: oncologic resectability and technical resectability. From an oncologic standpoint, complete resection of all viable disease is crucial if the patient is to derive the most benefit from surgery. The presence of extrahepatic disease does not necessarily represent an absolute contraindication for surgery. Isolated lung metastases have reportedly been associated with a high 5-year survival rate (30% to 40%) when complete resection is feasible. Localized peritoneal disease correlates with an intermediate 5-year survival rate (15% to 30%), whereas para-aortic adenopathy and evidence of multiple sites of extrahepatic disease are rarely associated with favorable survival after resection of CLM (5-year survival rate <15%).¹¹¹ These data suggest that patients harboring limited extrahepatic disease are amenable to surgical resection with a reasonable expectation for long-term control with adjuvant therapies.¹¹² However, when the extrahepatic disease is unresectable or uncontrollable with systemic chemotherapy, hepatic resection for CLM is contraindicated.

Another oncologically important factor in determining resectability is response to chemotherapy. With modern effective chemotherapy, disease progression during neoadjuvant systemic therapy is relatively rare. However, some patients present with tumor progression during preoperative systemic therapy. Growth of pre-existing intrahepatic metastases does not seem to be associated with poor outcomes. However, development of a new lesion is reportedly associated with a poor prognosis after resection of CLM.¹¹³ Therefore, the oncologic behavior of the tumor during preoperative chemotherapy

offers useful information to adequately stratify patients who would benefit from surgical resection.

From a technical standpoint, the resectability of CLM relies on anatomic considerations and underlying hepatic function. Because a safety limit for the extent of liver resection exists according to individual hepatic functional reserve, assessment of hepatic function and systematic volumetry of FLR are mandatory to estimate the risk of postoperative hepatic insufficiency and preoperative intervention to reduce the risk of surgery, as described later in this chapter. When the estimated FLR volume is smaller than the minimal FLR volume, to avoid postoperative hepatic insufficiency PVE or another approach, including two-stage resection, is considered.

Neuroendocrine Liver Metastases

Neuroendocrine tumors grow indolently and metastasize primarily to the liver. In the majority of the cases, these tumors are nonfunctioning and patients with a significant tumor burden can remain asymptomatic for years, while patients with minimal lesions can suffer various symptoms caused by excessive production of hormones by the tumor. Although the best treatment strategy has not yet been established, resection of functioning NETs reduces symptoms and prolongs survival. The survival rate of patients undergoing liver resection is relatively high, reaching 91% at 3 years¹¹⁴ and 61% at 5 years,^{115,116} even though the curative resection rate is relatively low. NETs are basically incurable in most advanced-stage cases. However, cytoreduction of >90% of the tumor volume is reportedly superior to other treatment options, such as transarterial embolization or systemic therapy.^{117,118} To maximize the treatment outcomes, a multidisciplinary approach that includes surgery, transarterial embolization, systemic chemotherapy, and radiation is needed.

PREOPERATIVE SURGICAL MANAGEMENT

When surgical resection is selected as an initial treatment for hepatic malignancy, secondary assessments for surgical planning and preoperative management are required.

Review of Vascular Anatomy

6 For surgical planning, precise anatomic interpretations of the intrahepatic vascular structures are needed. This step specifies the ramification pattern of each vascular structure based on the imaging studies and knowledge of anatomic variations.

Important variations in the portal venous system include its ramification patterns at the hepatic hilum. In approximately 80% of patients, the main portal vein bifurcates into the left and right portal branches at the hepatic hilum (bifurcation type). However, trifurcation into the left paramedian, right paramedian, and right lateral portal trunks at the hilum (10%) or early branching of the right lateral pedicle (10%) (trifurcation type) is frequently encountered in major hepatectomy. In addition, anomalies such as right-sided ligamentum teres (0.6% to 1.2%), lack of left portal trunk (0.9%), or lack of intrahepatic portal vein (<0.1%) are sometimes encountered. Because the portal ramification pattern defines the segmental anatomy of an individual liver, precise confirmation of the anatomy in the portal venous system is of primary importance.

As for the hepatic veins, attention should be paid to the drainage pattern of the right lateral sector (i.e., Segments VI + VII) because thick accessory right hepatic veins, such as the middle right hepatic vein or the inferior right hepatic vein,¹¹⁹ are observed in nearly 70% of cases. Care must be taken when these veins are thick and drain a large portion of Segment VI or VII because ligation of these veins may cause congestion of the right lateral sector and because careless handling of the right hemiliver during mobilization may cause incidental injury of these veins, resulting in massive bleeding (Fig. 60-11).

Regarding the hepatic arteries, the presence or lack of a “replaced” or “accessory” hepatic artery is important. Typically, both right and left hepatic arteries are derived from the proper hepatic artery. However, there are two frequent variations in the ramification patterns of the left and right hepatic arteries: the left hepatic artery sometimes branches from the left gastric artery, running in the lesser omentum and feeding Segments II and III, and the right hepatic artery sometimes originates from the superior mesenteric artery, running behind the portal vein and reaching the right hemiliver on the right side of the hepatic hilum. When the total arterial supply for the left lateral section (Segments II + III) or right hemiliver comes from these aberrant arteries, these arteries are called “replaced” arteries, while they are called “accessory” arteries when the other arterial flow from the proper hepatic artery is also present. Because of the presence of a typical arterial route derived from the proper hepatic artery,

accessory arteries can be ligated. In contrast, due to a lack of compensatory arterial supply from the proper hepatic artery, the replaced arteries should be preserved when the corresponding part of the liver is not resected. Therefore, preoperative review of the arterial anomalies in the early arterial phase in dynamic CT is essential, and a routine clamp test with Doppler ultrasound is needed before these aberrant arteries are ligated.

Figure 60-11. Multiple accessory right hepatic veins during liver mobilization. Intraoperative photo of the exposed right wall of the inferior vena cava during mobilization of the right lobe of the liver. IVC, inferior vena cava; RHV, right hepatic vein; MRHV, middle right hepatic vein; IRHV, inferior right hepatic vein. (Adapted from Shindoh J, Aoki T, Hasegawa K, et al. Donor hepatectomy using hanging maneuvers: Tokyo University experiences in 300 donors. *Hepatogastroenterology* 2012;59:1939–1943 with permission.)

Aside from the blood vessels, precise preoperative assessment of the biliary anatomy is difficult. There are considerable variations in the ramification pattern of the right-side biliary branches, while the anatomy of the left hepatic duct is rather simple and constant. Thus, right or extended right hepatectomy can be performed safely without any unnecessary injury to the biliary branches to be preserved. However, when left-side major hepatectomy is being performed, care should be paid not to injure the biliary branches for the right side. Magnetic resonance cholangiopancreatography may clarify the ramification pattern of the biliary tree. However, its imaging quality is not always satisfactory unless the intrahepatic bile duct is obstructed or dilated.

Based on this anatomic information and the tumor distribution, oncologically adequate types of resection can be planned and a safe vascular handling approach adopted. Conventionally, the quality of such meticulous anatomic assessments was highly dependent on the surgeon's knowledge or experience. However, with recent advancements in imaging modalities, three-dimensional reconstruction of CT images is easy and the three-dimensional liver simulation technique has provided ready access to the information on a patient's precise individual vascular anatomy (Fig. 60-12).¹²⁰

Assessment of the Minimal Requirement of FLR and CT Volumetry

The functional reserve of the liver depends on the quality of the liver parenchyma. The volume of the FLR^{4,14,121–123} and the regenerative capacity of the liver^{124,125} are important predictors of postoperative morbidity and mortality after extended hepatectomy. The minimal requirement of the FLR volume is determined by the balance between the hepatic functional capacity per volume and the actual volume of the FLR. The ICG clearance test is widely used to measure the hepatic functional reserve and to determine an adequate extent of surgery, especially for patients with cirrhosis. The landmark criteria for the maximum extent of resection proposed by Makuuchi et al.⁸² offer a simple algorithm to safely perform hepatic resection according to the ICG retention rate at 15 minutes (ICG-R15) (Algorithm 60-2), and the clinical relevance of this algorithm was validated in a large prospective cohort treated under the constant resection policy.¹ However, ICG-R15 has several limitations. First, it is used mainly to determine the extent of minor resection for patients with cirrhotic livers, and it does not offer a safety limit for major hepatectomy. Second, ICG-R15 is influenced by hepatic blood flow and measures performed after a meal, after exercise, or with patients with portosystemic shunts are not reliable. Third, because ICG is exclusively excreted in bile, the ICG test cannot be used for patients with obstructive jaundice or inherited hyperbilirubinemia. ^{99m}Tc-GSA, a scintigraphy agent that binds specifically to asialoglycoprotein receptors on hepatocytes, can be used to evaluate hepatic functional reserve. Because ^{99m}Tc-GSA scintigraphy is not influenced by the hepatic blood flow or biliary obstruction, it can be used to evaluate the hepatic functional reserve when the ICG clearance test is not

appropriate.

Figure 60-12. Three-dimensional evaluation of venous drainage areas. Three-dimensional volume assessment of venous drainage area predicts venous congestion area after deprivation of the corresponding hepatic venous branches or hepatic veins at surgery.

Evaluating the volume of the FLR is the most reliable approach to predicting outcome in patients who are candidates for major liver resection. Several methods have been described to evaluate the volume of the FLR. At The University of Texas MD Anderson Cancer Center, the standard liver volume (SLV) is estimated with a formula that relies on the linear correlation between the SLV and body surface area (BSA), as follows:

$$\text{SLV (cm}^3\text{)} = -794.41 + 1,267.28 \times \text{BSA (m}^2\text{)}$$

The standardized FLR (sFLR) is calculated as the ratio of the FLR volume divided by the SLV. In a series of 301 patients without chronic liver disease or hepatic injury who were undergoing extended right hepatectomy, an sFLR of <20% was a risk factor for postoperative liver insufficiency and 90-day postoperative mortality.⁴ Patients with chemotherapy-induced liver injury require an sFLR of approximately 30% and those with cirrhosis require at least 40% residual volume.^{13,14,121}

Of note, these volume criteria are based on the volume of the fully functioning hepatic parenchyma; in other words, the hepatic parenchyma with patent blood flow and intact biliary drainage. If combined resection of a hepatic vein is needed, the area with deprived venous drainage develops venous congestion and represents impaired hepatic function,^{126,127} resulting in atrophy of the corresponding area.^{128,129}

Portal Flow Modulation to Expand the Surgical Indication

7 PVE is a safe and minimally invasive procedure for inducing ipsilateral atrophy and compensatory contralateral hypertrophy of the FLR.^{130–133} When the sFLR volume is considered insufficient according to the baseline status of the underlying liver, PVE is considered to expand the surgical indication and to improve the safety of major hepatectomy (Fig. 60-13).

Several studies have demonstrated the efficacy of PVE in terms of hepatic functional shift from the embolized liver to the FLR and reduced surgical risk. First, a dynamic functional shift from the embolized liver to the FLR after PVE was confirmed in three studies using the ICG excretion rate,¹³⁴ ^{99m}Tc-GSA scintigraphy,¹³⁵ or bile clearance.¹³⁶ All of those studies indicated that PVE produced a clear functional shift from the embolized liver to the nonembolized FLR with a concomitant increase in FLR volume. Another study showed that when a patient achieved sufficient growth of the FLR to meet the minimum criteria for FLR volume, the operative risk was significantly reduced compared to the risk for patients who did not meet the minimum FLR volume criteria after PVE.⁴

sFLR after PVE sensitively predicts the risk of postoperative hepatic insufficiency. However, recent studies have indicated that the regeneration capacity or speed of regeneration independently predicts short-term surgical outcomes in patients undergoing PVE for a small FLR. Ribero et al.¹²⁴ reported that the degree of hypertrophy in sFLR volume after PVE is significantly associated with surgical outcomes. A degree of hypertrophy >5% after PVE along with sFLR >20% predicted good postoperative outcomes with high specificity and sensitivity in patients with normal liver function. The kinetic growth rate (defined as the degree of hypertrophy at initial volume assessment divided by the number of weeks

elapsed after PVE) sensitively predicts the risk of postoperative hepatic insufficiency. A kinetic growth rate $>2.0\%/week$ is strongly associated with a low risk of postoperative morbidity and mortality irrespective of the sFLR volume.¹²⁵

Figure 60-13. Example of right and segment IV portal vein embolization (PVE). Adequate hypertrophy of future liver remnant is observed from the standardized future liver remnant (sFLR) volume of 10% to 33% at 4 weeks after PVE.

Recently, a new short-interval, two-stage liver surgery technique was reported which consists of an initial open right portal vein ligation with in situ splitting of the liver parenchyma followed by reexploration for right trisectionectomy; this technique is called associating liver partition and portal vein ligation for staged hepatectomy (ALPPS).¹³⁷ The combination of portal vein ligation and in situ splitting of the liver to prevent cross-portal circulation between the lobes of the liver is believed to lead to profound hypertrophy of the FLR. However, preliminary data suggested a high incidence of major morbidity and inpatient mortality associated with this new procedure. The true efficacy of ALPPS in preventing postoperative hepatic insufficiency remains controversial and this procedure is still investigational.

SURGICAL TECHNIQUE

Exposure

8 Incision and exposure are key components of the quality of the exploration of the liver and the safety of hepatectomy. Various incisions – including the inverted-T (Mercedes) incision, bilateral subcostal (chevron) incision, right/left subcostal (Kocher/Kehr) incisions, J-shaped (Makuuchi) incision with or without thoracotomy, and inverted L-shaped (modified Makuuchi) incision (Fig. 60-14) – have been used to achieve these objectives. Recently evolved laparoscopic approaches may reduce the disadvantage of a large incision for hepatectomy. However, most hepatobiliary malignancies require complex surgical manipulations, including handling of the vena cava or major vessels just beneath the right atrium. Thus, hepatobiliary surgeons should be familiar with the traditional approaches for safe handling of the liver.

Figure 60-14. Inverted L-shaped incision and exposure. The inverted L-shaped (modified Makuuchi) incision. The incision begins cephalad to the xiphoid, extends to 1 cm above the umbilicus, and then extends laterally to the right. This incision achieves a superb en face view of critical structures, including the hepatocaval junction. (Adapted from Chang SB, Palavecino M, Wray CJ, et al. Modified Makuuchi incision for foregut procedures. *Arch Surg* 2010;145:281–284.)

Principles of Parenchymal Transection

The routine use of intraoperative ultrasonography has contributed to major improvements in liver resection techniques.¹³⁸ Intraoperative ultrasonography allows confirmation of the location of the tumors, the sites of intrahepatic anatomic structures, and the direction of transection. For anatomic resection of Couinaud segments, a segmental staining method with ultrasound guidance has been used to confirm the segmental border on the liver surface.

The key point in anatomic resection of the liver is exposure of the landmark vein on the cut surface of the liver. The three-dimensional shape of the intersegmental plane is not always flat and it varies considerably among individuals.^{36,139} However, the specific landmark vein for each intersegmental plane of the liver is consistent. Because the actual shape of the intersegmental plane is difficult to recognize during parenchymal transection without a special staining technique such as the ICG fluorescent technique¹⁴⁰ or contrast medium for ultrasound,¹⁴¹ the identification and exposure of the landmark vein on the cut surface of the liver is the only convincing technique that allows precise anatomic resection of the liver (Fig. 60-15).

For hepatic parenchymal transection, multiple techniques and devices are available to hepatobiliary surgeons, including clamps, staplers, jet cutters, ultrasonic aspirators (e.g., CUSA), saline-linked cautery (e.g., TissueLink), bipolar electrocoagulation devices, radiofrequency transection devices, harmonic scalpels, and microwave coagulators.^{142–145}

Control of Bleeding

Inflow occlusion at the hepatic hilum (Pringle maneuver) is widely used to reduce blood loss during hepatic parenchymal transection. Intermittent inflow occlusion (15 minutes of clamping and 5 minutes of release) has been proven to be a safe procedure even for living-donor surgery for liver transplantation.^{146,147} Under inflow occlusion, the amount of bleeding depends on the central venous pressure and the height of the manipulating point from the level of the inferior vena cava. Therefore, controlling central venous pressure by limiting the tidal volume and infusions in cooperation with anesthesiologists is important. In addition, adequate lifting of the hepatic parenchyma with the surgeon's left hand decreases back-bleeding during hepatic parenchymal transection.

Figure 60-15. Anatomic resection of Segments I + II + III + IV + VIII. This patient was found to have a huge HCC generated in the left hemiliver on underlying steatohepatitis. Because the tumor also extended to Segments I and VIII, compressing the right hepatic vein and hepatic hilum, left trisectionectomy was considered to be the most optimal approach. However, due to impaired hepatic functional reserve (ICG-R15, 17%), the future liver remnant (i.e., right lateral sector) was considered too small (<30% vs. standard liver volume). Therefore, Segment V was preserved with a staining technique. **Top left:** Puncture of Segment VIII portal pedicle under ultrasound guidance and injection of indigocarmine (arrow). **Top right:** Segment VIII was clearly stained on the surface of the liver (arrowheads). **Bottom left:** transection line for anatomic Segments I + II + III + IV + VIII resection was marked by cautery. **Bottom right:** completion of anatomic resection fully preserving Segments V, VI, and VII. The right hepatic vein is exposed on the cut surface of the liver (arrows).

Figure 60-16. Retrohepatic dissection and hanging maneuver during anterior approach. **Left:** The avascular plane between the liver and the inferior vena cava is dissected and a tape is placed. **Right:** Traction of the tape during parenchymal transection allows adequate control of bleeding from the deeper transection plane of the liver. (Adapted from Donadon M, Abdalla EK and

When conventional mobilization of the liver is difficult prior to parenchymal transection due to tumor invasion of the diaphragm on the right side of the liver, parenchymal transection needs to be preceded by mobilization of the right lobe (anterior approach). To control bleeding at the deeper part of the liver parenchyma in such cases, the hanging maneuver proposed by Belghiti et al.¹⁴⁸ is widely used. This maneuver involves dissecting the retrohepatic avascular space between the liver and the inferior vena cava and placing a tape for lifting the liver. By retracting the tape during parenchymal transection, squeezing pressure can be applied on the deep transection plane and may reduce bleeding (Fig. 60-16).

Bile Leak Test

Bile leak from the cut surface of the liver is a frequent major complication observed after liver resection and requires postoperative drainage according to the degree of leakage (Table 60-3).¹⁴⁹ Even though various intraoperative tests have been tried, bile leaks are still reported in up to 8% of patients who have undergone liver resection. Although it can be treated with adequate drainage, bile leak increases the risk of sepsis and hepatic insufficiency. One group recently assessed the efficacy of transcystic injection of air into the biliary system to test the patency of the biliary tract and to detect any air leak from the major ducts of the parenchymal transection surface (Fig. 60-17) and found that postoperative bile leak decreased from 10.8% to 1.0% ($p = 0.008$) with adequate use of a bile leak test after completion of hepatectomy.¹⁵⁰

Staged Surgery

When the liver tumor burden is limited, including small tumors and anatomically favorably positioned bilateral metastases, a one-stage strategy involving one or more simultaneous partial hepatectomies in lobar hepatic resection is safe and effective.^{151–156} In contrast, when extensive bilobar metastases are present, different surgical strategies are required.

Figure 60-17. Air leak test for detection of bile leak. **Left:** With injection of air into the biliary tract, the point of bile leak can be sensitively detected as an air leak point (arrows). **Right:** Patency of the bile duct can be confirmed as pneumobilia on ultrasound image. (Adapted from Zimmitti G. Systematic use of an intraoperative air leak test at the time of major liver resection reduces the rate of postoperative biliary complications. *J Am Coll Surg* 217;1028–1037, with permission.)

Table 60-3 Definition and Grades of Bile Leak After Liver Resection by International Study Group of Liver Surgery (ISGLS)

Definition	Bile leakage is defined as fluid with an increased bilirubin concentration in the abdominal drain or in the intra-abdominal fluid on or after postoperative day 3, or as needed for radiologic intervention (i.e., interventional drainage) because of biliary collections or relaparotomy resulting from bile peritonitis. Increased bilirubin concentration in the drain or intra-abdominal fluid is defined as a bilirubin concentration at least three times greater than the serum bilirubin concentration measured at the same time.
Grade	
A	Bile leakage requiring no or little change in patients' clinical management
B	Bile leakage requiring a change in patients' clinical management (e.g., additional diagnostic or interventional procedures) but manageable without relaparotomy, or a grade A bile leakage lasting for >1 wk
C	Bile leakage requiring relaparotomy

Adapted from Koch M, Garden OJ, Padbury R, et al. Bile leakage after hepatobiliary and pancreatic surgery: a definition and grading of severity by the International Study Group of Liver Surgery. *Surgery* 149:680–8, 2011 with permission.

Two-stage liver resection is a reasonable approach for patients with advanced bilateral CLM who responded to chemotherapy and in whom limited resection could clear the less affected side of the liver before a planned extended contralateral liver resection. Patients undergo first-stage limited resection of metastases in the left lobe that is followed by right PVE with or without Segment IV embolization to allow hypertrophy of the FLR. Then, extended right hepatectomy is completed after the sFLR meets the volume criteria. A previous study reported that 72.3% of the patients with planned two-stage liver resection completed the second-stage resection and the 5-year survival of these patients was 51% but 15% in the cases treated with chemotherapy alone.¹⁵⁷

The ALPPS procedure is a similar approach in which right portal vein ligation and parenchymal transection at the time of first resection is performed instead of PVE. This procedure seems to offer rapid growth of the FLR compared with conventional PVE. However, because the safety of this new approach and the detailed techniques are still under investigation, clinical application should be limited to highly selected patients at high-volume hepatobiliary centers.

Laparoscopic Liver Resection

9 The laparoscopic approach for liver resection has evolved since the early 1990s^{158–161} and its feasibility has since been established, especially for patients undergoing partial hepatectomy or left lateral segmentectomy.^{162–165} Although this approach has benefits, including less postoperative pain, earlier recovery, and shorter length of hospital stay compared to the conventional open approach,^{166–169} it requires experience with an open approach and advanced techniques in laparoscopic surgery. Because the liver is a large, heavy organ, mobilization and parenchymal transection require advanced skill in a limited surgical field. Recently, several centers have reported on the feasibility of the laparoscopic approach for major hepatectomy or graft procurement of living donors for liver transplantation; however, these complex laparoscopic procedures should not be approached by surgeons without significant laparoscopic liver surgery experience. In addition, for patients with hepatic malignancies, oncologic curability should be secured if the laparoscopic liver resection is adopted. Therefore, the indication for laparoscopic approach should be determined according to the technical feasibility, the surgeon's surgical skill, and the oncologic curability of the tumors.

Liver Transplantation

Liver transplantation is a reasonable approach with a theoretically higher chance of eradication of tumors, especially for patients with severe hepatic dysfunction. However, because of the negative impact of posttransplant immunosuppression on tumor recurrence or progression, liver transplantation was originally thought to be a contraindication for hepatic malignancy. More recent experience with liver transplantation for hepatoblastoma in children¹⁷⁰ or early-stage HCC⁷⁷ has led to cautious application of liver transplantation for hepatic malignancies. As we mentioned previously, several high-volume transplant centers have used their original expanded criteria for liver transplantation for HCC,^{86–97,171} although these criteria have not yet been standardized and HCC meeting the Milan criteria remains a standard indication for liver transplantation.

Liver transplantation has also been used in selected patients with other hepatobiliary malignancies, such as NET,^{172–174} epithelioid hemangioendothelioma,¹⁷⁵ colorectal cancer,¹⁷⁶ and hilar cholangiocarcinoma.^{177,178} However, the clinical evidence remains limited and true efficacy over other nonsurgical treatments has not yet been proven.

SUMMARY

Despite recent advances in the nonsurgical treatment of hepatic neoplasms, surgical resection still plays a pivotal role. In the era of effective chemotherapy and interventional radiology, primary unresectable tumor can become resectable during the treatment course, especially for CLM. However, oncologic curability and surgical safety are, by nature, conflicting factors. Comprehensive assessment of the oncologic characteristics, the hepatic lesions, and the status of the underlying liver is essential for proper risk management and for selecting candidates with the greatest survival benefit from surgical resection.

Chapter 61

Calculous Biliary Disease

David A. Kooby, Joshua H. Winer, and Kenneth Cardona

Key Points

- 1 Gallstones are classified by their cholesterol content as either cholesterol (70% to 80%) or pigment (20% to 30%), with pigment stones further classified as black or brown.
 - 2 Biliary sludge refers to a mixture of cholesterol crystals, calcium bilirubinate granules, and a mucin gel matrix and is thought to serve as the nidus for gallstone growth.
 - 3 The pathogenesis of cholesterol gallstones is clearly multifactorial but essentially involves four factors: (a) cholesterol supersaturation in bile, (b) crystal nucleation, (c) gallbladder dysmotility, and (d) gallbladder absorption/secretion.
 - 4 Prophylactic cholecystectomy is generally not indicated in patients with asymptomatic gallstones, because studies show that under 30% of patients will become symptomatic within 20 years and only 1% to 2% will develop gallstone-related complications, such as cholecystitis, per year.
 - 5 Elective laparoscopic cholecystectomy is associated with a mortality rate of less than 0.3% and an overall complication rate of 10%, with less than 5% of patients requiring conversion to an open procedure.
 - 6 Randomized trials have shown that laparoscopic cholecystectomy performed for acute cholecystitis (AC) during initial hospitalization can be performed safely resulting in a lower morbidity rate and shorter overall hospital stay when compared to delayed cholecystectomy during a separate admission.
 - 7 Common bile duct (CBD) stones, similar to gallbladder stones, can have an asymptomatic course and pass spontaneously without clinical consequence. When symptomatic, the presentation of CBD stones can vary between mild biliary colic to fulminant sepsis from acute cholangitis, biliary pancreatitis, or hepatic abscesses.
 - 8 ERCP with stone extraction is effective in removing stones in 85% to 95% of cases but is associated with postprocedural complications (pancreatitis and cholangitis) in 5% of cases.
 - 9 Endoscopic cholangiography with sphincterotomy allows for the diagnosis of CBD stones in the vast majority of cases. The primary advantage of endoscopic retrograde cholangiopancreatography (ERCP) is that it allows for therapeutic intervention if stones are identified.
 - 10 Acute cholangitis results from the combination of significant bacterial concentration in bile and increased biliary pressure associated with biliary obstruction.
-

INTRODUCTION

Cholelithiasis (gallbladder stone disease) is both a substantial healthcare problem and financial burden for the US healthcare system, with more than 20 million Americans afflicted, resulting in expenses of more than 6 billion dollars annually.¹ A recent report demonstrates that cholelithiasis and cholecystitis were the second most common gastrointestinal problems listed as the discharge diagnosis in 2009 with approximately 750,000 gallbladders removed.² Surgeons treating patients with gallstones and their associated conditions should have an understanding of biliary physiology and of the pathophysiology of gallstone formation. This chapter reviews the physiology and surgical management of calculous biliary disease.

BILIARY PHYSIOLOGY

An understanding of normal bile composition, synthesis, and metabolism is pertinent to the

understanding of gallstone formation.

Bile Composition and Function

Healthy livers produce between 600 and 750 mL of bile per day. Normal bile is composed of bile acids (or salts, 61%), fatty acids (12%), cholesterol (9%), proteins (7%), phospholipids (3%), bilirubin (3%), and other substances (5%).³ Bilirubin is the breakdown product of spent red blood cells and is conjugated with glucuronic acid prior to being excreted. Bile acid components can be further subclassified as primary bile acids and secondary bile acids. Primary bile acids (cholic and chenodeoxycholic acids) are synthesized in the liver and secondary bile acids (deoxycholic and lithocholic acids) represent primary bile acids that undergo deconjugation in the gut by bacteria. Cholesterol is produced primarily by the liver with little contribution from dietary sources, and is highly nonpolar and insoluble in water and thus in bile, as well. Phospholipids (95% phosphatidylcholine in healthy individuals) are synthesized in the liver in conjunction with bile salt synthesis. Percentages of biliary phospholipid and cholesterol vary with underlying liver disease.

Bile facilitates the intestinal absorption of lipids, fat-soluble vitamins and various drugs, and promotes excretion of certain organic solids, such as bilirubin and cholesterol. Bile acids solubilize lipids and facilitate their absorption and excretion through emulsification of dietary fats. More recent evidence shows that bile acids regulate their own synthesis, perform various endocrine and autocrine functions, and serve as ligands for various nuclear receptors involved in carbohydrate, triglyceride, and sterol metabolism.⁴ Bile acids also interact with cell surface receptors involved in glucose and lipid metabolism, energy consumption, and immune response.⁵

The potency of bile is increased through the process of concentration (5 to 10×) within the gallbladder, as electrolytes, water, and calcium are reabsorbed (Table 61-1). Sodium chloride channels actively transport salt across the epithelium efficiently⁶ and water follows passively in response to the resultant osmotic force. Calcium absorption is less efficient, resulting in a net increase in calcium percentage in stored bile. As gallbladder bile becomes concentrated, the capacity of bile to solubilize cholesterol lessens. Solubility of the micellar fraction is increased; however, solubility of phospholipid-cholesterol vesicles is reduced. It is the vesicular fraction of vesicular cholesterol combined with the increased concentration of calcium in the gallbladder lumen that promotes development of cholesterol crystals and subsequent gallstones.

Table 61-1 Composition of Hepatic and Gallbladder Bile

Characteristic	Hepatic	Gallbladder
Sodium (mEq/L)	160	270
Potassium (mEq/L)	5	10
Chloride (mEq/L)	90	15
Bicarbonate (mEq/L)	45	10
Calcium (mEq/L)	4	25
Magnesium (mEq/L)	2	—
Bilirubin (mEq/L)	1.5	15
Protein (mEq/L)	150	—
Bile acids (mEq/L)	50	150
Phospholipids (mEq/L)	8	40
Cholesterol (mEq/L)	4	18
Total solids (mEq/L)	—	125
pH	7.8	7.2

Enterohepatic Circulation

Bile acids travel in the bile through the liver, biliary tree, intestines, and the portal venous circulation to return to the liver, thereby recovering 95% of bile acids, with the other 5% passing in stool. Hepatocytes secrete bile acids through a rate-limiting, ATP-dependent process via a bile salt export pump. Approximately 600 to 750 mL of bile is produced daily. Hormones, such as secretin, cholecystokinin (CCK), and gastrin increase bile flow primarily by promoting active secretion of chloride-rich fluid in the bile ducts.

Gallbladder Function

The main functions of the gallbladder are to concentrate and store bile during the fasting state and deliver bile into the duodenum when needed. Bile reenters the distal bile duct and is secreted into the duodenum in response to a meal. The gallbladder mucosa is unique in that it has the greatest absorptive capacity per unit of any structure in the body, but the gallbladder itself has a limited storage capacity of approximately 50 mL; thus the bile it can store is made more effective through the process of concentration.

The gallbladder's mucosa secretes mucous glycoproteins and hydrogen ions. Mucous glycoproteins are actively secreted from the mucosal glands in the gallbladder neck and cystic duct. The resultant mucous barrier protects the gallbladder epithelium from the detergent effect of concentrated bile salts. The transport of hydrogen ions by the gallbladder epithelium leads to a decrease in bile pH through an active sodium-exchange mechanism. Acidification of bile in the gallbladder promotes calcium solubility, thereby preventing its precipitation as calcium salts and subsequent gallstone formation. The gallbladder's normal acidification process lowers the pH of hepatic bile from 7.5 to 7.8 down to 7.1 to 7.3.⁷

Biliary Motility

Gallbladder filling is facilitated through tonic contraction of the ampullary sphincter, which maintains a constant pressure in the common bile duct (CBD) (10 to 15 mm Hg). There are periods of gallbladder filling flanked by brief periods of partial emptying (10% to 15% of its volume) of concentrated bile. These emptying periods are coordinated with each passage of chyme through the duodenum via the migrating myoelectric complex (MMC) and the hormone motilin. Following a meal, the release of stored bile from the gallbladder requires coordination of both gallbladder contraction and sphincter of Oddi relaxation. CCK is released from the duodenal mucosa in response to a meal, and this hormone serves as a major stimulus for gallbladder contraction. Following a meal, the gallbladder releases 50% to 70% of its contents within 30 to 40 minutes. Gallbladder refilling then occurs gradually over the next 60 to 90 minutes. Many other hormonal and neural pathways are also necessary for the coordinated action of the gallbladder and sphincter of Oddi. Dysmotility of the gallbladder increases the time bile dwells in the gallbladder, and along with calcium precipitation, plays a central role in the pathogenesis of gallstones.⁸

Sphincter of Oddi

The human sphincter of Oddi is a complex structure that is functionally independent from the duodenal musculature. Endoscopic manometric studies demonstrate that the sphincter of Oddi creates a high-pressure zone between the bile duct and the duodenum, which regulates the flow of bile and pancreatic juice into the duodenum while preventing regurgitation of duodenal contents into the biliary tract. Through this action, a higher luminal pressure is maintained in the biliary tract than in the duodenal lumen.

Both neural and hormonal factors influence the sphincter of Oddi. In humans, sphincter of Oddi pressure and phasic wave activity diminish in response to CCK. Thus, sphincter pressure relaxes after a meal, allowing the passive flow of bile into the duodenum. During fasting, high-pressure phasic contractions of the sphincter of Oddi persist through all phases of the MMC. Results of animal studies demonstrate that sphincter of Oddi phasic waves do vary with the MMC, permitting partial gallbladder emptying and increasing bile flow during phase III of the MMC; a mechanism which may serve to limit accumulation of biliary crystals during fasting.⁹ Neurally mediated reflexes link the sphincter of Oddi with the gallbladder and stomach to coordinate the flow of bile and pancreatic juice into the duodenum. The cholecystosphincter of Oddi reflex allows the sphincter to relax as the gallbladder contracts. Similarly, antral distention causes both gallbladder contraction and sphincter relaxation.

GALLSTONES

Ten to 20% of adults in the United States will be affected by gallstones during their lifetime.¹⁰ The vast majority of people with gallstone will have asymptomatic disease diagnosed incidentally via imaging (ultrasound [US], computed tomography [CT], or magnetic resonance imaging [MRI]) for other health problems. It is estimated that 2% to 3% per year of those with known gallstones will develop symptoms¹¹ and 1% to 2% will develop more complex problems such as cholecystitis, pancreatitis, or cholangitis annually.¹² Gallstones represent a failure to maintain certain biliary solutes, primarily

cholesterol and calcium salts, in a solubilized state, and can form in the gallbladder and less commonly in the bile ducts.

Gallstone Formation

1, 2 The gallbladder fills with hepatic bile during tonic contraction of the ampullary sphincter. Following a meal, the duodenum releases the gut peptide CCK, which stimulates gallbladder emptying. Fifty to 70% of the gallbladder contents are forced into the duodenum and then refilling gradually happens within the next 60 to 90 minutes.¹³ The combination of hepatic bile acidification and concentration in the gallbladder, by 5 to 10-fold, enhance calcium solubility; however, the secretion of mucous glycoproteins to protect the mucosa from bile salts serves as a nidus for cholesterol stone formation. An important biliary precipitate in gallstone pathogenesis is biliary “sludge,” which refers to a mixture of cholesterol crystals, calcium bilirubinate granules, and a mucin gel matrix. Biliary sludge has been observed clinically in prolonged fasting states or with the use of long-term total parenteral nutrition (TPN). Both of these conditions are also associated with gallstone formation. The finding of macromolecular complexes of mucin and bilirubin, similar to biliary sludge in the central core of most cholesterol gallstones, suggests that sludge may serve as the nidus for gallstone formation.

Figure 61-1. A: Cholesterol gallstones. B: Black pigment gallstones. C: Brown pigment gallstones.

Gallstone Types

3 Gallstones are classified by their cholesterol content as either cholesterol or pigment stones. Pigment stones are further classified as either black or brown (Fig. 61-1). In most American populations, 70% to 80% of gallstones are cholesterol stones and the others are black pigment stones.

Cholesterol Gallstones

Pure cholesterol gallstones are uncommon, as most have a core of calcium salts (90%). The pathogenesis of cholesterol gallstones involves four key factors: (a) cholesterol supersaturation in bile, (b) crystal nucleation, (c) gallbladder dysmotility, and (d) gallbladder absorption/secretion.

Cholesterol Supersaturation. The key to maintaining cholesterol in solution is the formation of micelles, a bile salt–phospholipid–cholesterol complex, and cholesterol–phospholipid vesicles (Fig. 61-2). Present theory suggests that in states of excess cholesterol production, these large vesicles may

exceed their capability to transport cholesterol and crystal precipitation may occur. Cholesterol solubility depends on the relative concentration of cholesterol, bile salts, and phospholipid. By plotting the percentages of each component on triangular coordinates, the micellar zone in which cholesterol is completely soluble can be demonstrated (Fig. 61-3). In the area above the curve, bile is supersaturated with cholesterol and precipitation of cholesterol crystals can occur.

Figure 61-2. Phases of cholesterol in bile.

Figure 61-3. Equilibrium phase diagram for bile salt-lecithin-cholesterol-water at a concentration of 10% solids, 90% water. The monomeric phase is not depicted as a phase because it exists at the same concentration throughout. The one-phase zone contains only micelles. Several other zones exist, but only the two on the left above the one-phase zone apply to human gallbladder bile, and both contain cholesterol monohydrate crystals at equilibrium.

Cholesterol Crystallization. Cholesterol supersaturation does not always result in stone formation. As bile is concentrated in the gallbladder, a net transfer of phospholipids and cholesterol from vesicles to micelles occurs. The phospholipids are transferred more efficiently than cholesterol, leading to cholesterol enrichment in the vesicles. These cholesterol-rich vesicles aggregate to form large multilamellar liquid vesicles that then precipitate cholesterol monohydrate crystals. Several pronucleating factors including mucin glycoproteins, immunoglobulins, and transferrin accelerate the precipitation of cholesterol in bile.

Gallbladder Motility. For gallstones to cause clinical symptoms, they must obtain a size sufficient to produce mechanical injury to the gallbladder or obstruction of the biliary tree. Growth of stones may occur in two ways: (a) progressive enlargement of individual crystals or stones by deposition of additional insoluble precipitate at the bile-stone interface, or (b) fusion of individual crystals or stones to form a larger conglomerate. Poor gallbladder motility increases the dwell time of bile in the gallbladder, further promoting stone formation. Clinical conditions associated with reduced gallbladder motility include prolonged fasting, long-term TPN administration, surgical vagotomy, diabetes mellitus, and supratherapeutic levels of somatostatin resulting from either somatostatin-producing tumors or in patients receiving long-term somatostatin therapy.

Gallbladder Absorption/Secretion. Alterations in sodium, chloride, bicarbonate, and water

absorption may alter the milieu for cholesterol saturation and crystal formation as well as for calcium precipitation.¹⁴

Pigment Gallstones

Pigment gallstones are classified as either brown or black pigment stones.

Brown Pigment Stones. These stones are composed of calcium bilirubinate, fatty acid soaps (calcium palmitate and calcium stearate), cholesterol, and mucinous glycoproteins (products of bacterial biofilms). They are earthy in texture and are typically found in the intrahepatic and extrahepatic bile ducts (as opposed to the gallbladder) in states of increased bile duct stasis, such as sclerosing cholangitis, congenital biliary cystic disease, chronic biliary strictures, chronic pancreatitis, duodenal diverticula, and infections with bacteria or biliary parasites. East Asian populations are particularly at risk of brown stone formation due to susceptibility to *oriental cholangiohepatitis* (recurrent pyogenic cholangitis). In this condition, bacteria produce a biofilm rich in glucuronidase, which hydrolyses conjugated bilirubin to free bilirubin. Free bilirubin precipitates when mixed with calcium.

In these settings, bacteria-producing slime and bacteria containing the enzyme glucuronidase cause enzymatic hydrolysis of soluble conjugated bilirubin glucuronide to form free bilirubin, which then precipitates with calcium leading to stone formation.

Black Pigment Stones. These stones form primarily in the gallbladder in sterile bile and are associated with advanced age, chronic hemolysis, alcoholism, cirrhosis, pancreatitis, and total parenteral nutrition, and are typically tarry. These stones are usually not associated with infected bile and are located almost exclusively in the gallbladder.

INDICATIONS FOR CHOLECYSTECTOMY

Asymptomatic Patients

4 Given that the large majority of individuals with gallstones are asymptomatic and have no associated complications, most patients can be managed expectantly without surgical intervention. Prophylactic cholecystectomy may, however, be indicated in certain circumstances (Table 61-2). Patients who have a higher risk of cancer in the setting of gallbladder disease, such as Native Americans, presence of large gallstones (>2.5 cm), or calcification of gallbladder wall (“porcelain gallbladder”) are commonly offered prophylactic cholecystectomy. Patients who are more likely to have recurrent symptoms or complications secondary to gallstone disease may also undergo prophylactic cholecystectomy; examples of these conditions include hereditary spherocytosis, sickle cell disease, other hemoglobinopathies, the bariatric patients, and pediatric patients. Finally, some clinicians argue that organ transplant patients with gallstones should undergo pretransplant prophylactic cholecystectomy given the possible higher risk of developing complicated gallstone disease due to chronic immunosuppression.

Patients with asymptomatic gallstones who are not offered a cholecystectomy, or choose not to undergo an operation, can be managed with other therapies. In patients with small gallstones (<5 mm) oral dissolution therapy with bile salts may be utilized.²² Ursodeoxycholic acid (ursodiol) appears to work by dissolving cholesterol crystals and decreasing hepatic secretion of biliary cholesterol thereby decreasing the number of stones. It is also thought that this would decrease the number of colic attacks. Unfortunately, the majority of stones recur (>50% at 5 years) and in a prospective randomized study of 177 patients from the Netherlands, a country that has a long waiting list for elective biliary procedures, ursodiol did not decrease the number of attacks nor gallstone-related complications during the waiting period for cholecystectomy.²³

Table 61-2 Indications for Prophylactic Cholecystectomy

Pediatric gallstones
Congenital hemolytic anemia
Gallstones >2.5 cm in diameter
Calcified (porcelain) gallbladder (risk of cancer ~5–6% ^{15–17})
Bariatric surgery (controversial) ^{18,19}
Long common channel of bile and pancreatic ducts ^{20,21}
No access to medical care

Table 61-3 Natural History of Gallstones

Degree of Symptoms	Symptoms Requiring Cholecystectomy	Complications of Gallstones
Asymptomatic	1–2%/yr	1–2%/yr
Mild symptoms	6–8%/yr	1–3%/yr
Symptomatic	5–30%/yr	7/yr

An additional therapy, although not commonly employed, is extracorporeal shock wave lithotripsy (ESWL). This therapy uses energy (“shock”) waves, produced by different methods depending on the generator technology, to dissolve stones. ESWL can dissolve small calculi or decrease the size of larger calculi and make them potentially extractable by endoscopic or percutaneous techniques, if in the CBD or distal cystic duct, or dissolvable by oral therapy if present in the gallbladder. It is a relatively safe procedure with rare complications, including: hematoma (biliary or otherwise), bowel perforation, and necrotizing pancreatitis.²⁴

Symptomatic Patients

It is estimated that 2% to 3% per year of those with known gallstones will develop symptoms¹¹ and 1% to 2% will develop more complex problems (such as cholecystitis, pancreatitis, or cholangitis) annually (Table 61-3).¹² Those who develop symptoms will most often have biliary colic, or right upper quadrant (RUQ) pain, which will often recur. Biliary colic will often last for several hours after onset before subsiding. Biliary colic develops secondary to intermittent impaction of gallstones at the gallbladder neck as the gallbladder contracts in order to deliver its contents into the CBD. In more than 50% of patients it occurs following a fatty meal. Biliary colic can be associated with belching, bloating, and even nausea or emesis. Over time this intermittent obstruction leads to increased tension in the gallbladder wall and more chronic pain and inflammation known as chronic cholecystitis.

COMPLICATED GALLSTONE-RELATED DISEASE

Complicated gallstone-related disease (acute cholecystitis [AC], choledocholithiasis, and associated consequences of gallstone pancreatitis or cholangitis) will occur in 0.3% to 3% of patients per year.²⁵ These complications increase the morbidity and potential mortality of patients with gallstones.

Acute Cholecystitis

AC develops when a gallstone(s) lodges in the gallbladder neck (infundibulum) obstructing bile flow into the CBD. This obstruction leads to biliary stasis, gallbladder wall edema, venous obstruction, and in extreme cases, eventual arterial obstruction causing necrosis of the gallbladder wall. Its course can range from mild pain with fevers to frank sepsis secondary to perforation or development of emphysematous/gangrenous cholecystitis. Clinically, patients present in a similar manner to those with biliary colic; however the pain is constant, unrelenting, and often associated with fevers, tachycardia, and a leukocytosis. The diagnosis is typically made with a thorough history and physical examination, in which the patient may present with midepigastria or RUQ pain, as well as, localized peritoneal irritation. *Murphy’s sign*, which is defined by cessation of inspiration secondary to pain, due to the presence of an inflamed gallbladder during deep abdominal palpation at the midclavicular line of the RUQ, is pathognomonic for AC.

Imaging and Diagnosis

A variety of imaging tests can be used when evaluating the patient with AC, each of which have different strengths and weaknesses, and serve as an adjunct to a thorough history and physical examination.

Ultrasound (US) uses oscillating sound waves to measure differences in tissue densities and interfaces between liquids and solids and is the backbone of imaging for gallstone disease (Fig. 61-4). The primary advantages of US are that it is readily available, quickly performed, and avoids ionizing radiation. The main disadvantage is that it is user-dependent, and technique and experience are therefore quite important.²⁶ AC can be diagnosed by various US criteria, with the higher number of criteria met on US examination, the more likely for cholecystitis to be present. These criteria include gallbladder wall thickening >5 mm, pericholecystic fluid, gallstones, and a positive sonographic *Murphy sign*

characterized by pain and cessation of inspiration when the probe is pressed over the gallbladder. A 2012 meta-analysis by Kiewiet et al.²⁷ which included 26 studies with 2,847 patients, evaluated the role of US as a tool to diagnose AC, and reported a sensitivity of 81% and specificity of 83% with the comparison being against surgical pathologic findings in the majority of patients.

HIDA scan (biliary scintigraphy) first came into use in the late 1970s.²⁸ The injectable radioactive dye (derivatives of technetium and iminodiacetic acid) used is preferentially taken up by the liver and excreted into the bile and should fill both the CBD and gallbladder if there is free flow through the entire biliary system. A HIDA scan is considered positive for AC if there is lack of visualization of the gallbladder due to cystic duct occlusion from gallstones which does not allow the radioactive tracer to enter the gallbladder (Fig. 61-5). The overall sensitivity for AC of a HIDA scan is 95% to 98% with a specificity of >90%.^{27,28} A false-positive HIDA scan can occur in various situations, including consumption of a recent meal (the gallbladder is contracted due to CCK), prolonged fasting (the gallbladder has concentrated thick bile which acts as a mechanical obstruction to entrance of the tracer), chronic cholecystitis, or the presence of underlying hepatobiliary disease.

Limitations of HIDA scans are that it is not always readily available, especially after hours, and require exposure to ionizing radiation; thus, most clinicians will begin with US and then use HIDA to clarify equivocal US results. Several studies have looked at the utility of adding HIDA to US in the case of diagnostic dilemma, but the combined modalities do not appear to add sensitivity or specificity for detection of AC, although they may provide additional morphologic information.²⁹⁻³¹

CT scans are typically less helpful for diagnosing uncomplicated gallstone disease, as most gallstones (85%) are not radiopaque. CT scans are limited in their ability of evaluating the CBD and identifying an obstruction of the cystic duct, which is a prerequisite for the diagnosis of AC.^{26,32-34} They have been shown to be less sensitive and specific than US.³² CT scans can be helpful, however, in evaluating patients for complications of AC (Fig. 61-4). Gangrenous cholecystitis, which is the most common AC complication, occurs in up to 38% of patients with AC. Gallbladder perforation and abscess formation can be seen in up to 8% to 12% of AC cases. A CT scan can detect a defect in the gallbladder wall in 53% of patients with early perforation whereas US cannot easily delineate a mural defect, unless large, although both will likely help detect the resulting abscess formation (Fig. 61-6).

Figure 61-4. Classic acute cholecystitis seen on US (A) with luminal distention, gallbladder wall thickening >5 mm, and pericholecystic fluid; CT scan (B) demonstrates similar findings of wall thickening and pericholecystic stranding; MRI T2 fat-saturated sequence (C) demonstrates gallbladder wall edema and pericholecystic fluid, as well as small stones in the gallbladder neck. (Image courtesy of Aarti Sekhar, MD and David Schuster, MD, Emory University Department of Radiology.)

MRI has only been evaluated in small studies in the setting of AC. Its sensitivity and specificity are similar to that of US (approximately 80% to 85% for both). MRI is useful for evaluation of the biliary tree and to assess for the presence of choledocholithiasis; however, it can overestimate the presence of gallbladder wall inflammation (Fig. 61-4). Advancements in MRI protocols employing unique tracers that are taken up and excreted in the biliary tree similar to iminodiacetic acid compounds, such as Eovist, are currently under investigation.³⁵ Ultimately, the current cost and availability of MRI machines make it of limited use for the diagnosis of AC.

Treatment

The treatment of AC can consist of medical or surgical therapies and the correct treatment modality will depend on the individual clinical scenario. The medical treatment of AC involves nothing *per os*, parenteral hydration, and antibiotics until the patient’s clinical examination improves and pain resolves. The diet is then slowly advanced and the patient is kept on a low-fat diet until cholecystectomy is performed. Despite symptom resolution, the patient should undergo an *interval* cholecystectomy, as the likelihood of a second biliary-related complication is high. Surgical therapy consists of either a laparoscopic or open cholecystectomy, or placement of a cholecystostomy tube in combination with medical therapy.

5 Cholecystectomy. Cholecystectomy is considered standard therapy for patients with symptomatic gallstones and AC. With regard to the surgical treatment of AC, the discussion in the literature has been the timing of the cholecystectomy – early versus delayed. Early cholecystectomy removes the pathologic source, usually within the first 72 hours of presentation. Certain clinicians advocate for delayed cholecystectomy to allow the acute inflammatory response to resolve potentially making the surgery safer with fewer complications and morbidity, such as bile duct injuries, bleeding, and conversion from laparoscopic to open procedure.

Figure 61-5. HIDA scan (A) demonstrating positive result with uptake of tracer within liver and excretion through the common bile duct with filling of the duodenum, but absence of filling of gallbladder (*arrowhead*) even on delayed postmorphine imaging (B), confirming cystic duct occlusion. Final panel (C), shows normal filling of gallbladder (*arrow*), or a negative result. (Image courtesy of Aarti Sekhar, MD and David Schuster, MD, Emory University Department of Radiology.)

Figure 61-6. Examples from two patients with focal perforations of the gallbladder wall seen on US (A) and CT scan (B). Large perforations are visible with either modality, but CT is more sensitive for detecting smaller perforations. (Image courtesy of Aarti Sekhar, MD and David Schuster, MD, Emory University Department of Radiology.)

6 A 2006 meta-analysis showed no significant differences in patient outcomes between early and delayed surgeries with respect to bile duct injuries, bleeding complications, laparoscopic-to-open conversion, postoperative infection, and patient death.³⁶ It was noted that over 23% of delayed patients presented with complications requiring emergent cholecystectomy. Furthermore, total hospital stay, including the index admission and subsequent admissions for biliary complications and later cholecystectomy, was significantly shorter for early cholecystectomy, leading to a decreased cost to the patient and system.

Early has also been somewhat of a misnomer, as traditionally this early approach has consisted of performing a cholecystectomy within 72 hours of the onset of symptoms. A Cochrane review in 2006,³⁷ which included 6 randomized trials with 488 patients, compared early (within 7 days of presentation) to late (>6 weeks after initial treatment) cholecystectomy and found similar results to the above meta-analysis with no increase in terms of complications and outcomes. Multiple studies demonstrate that *early* should be within the index admission and the 72-hour limit is not as much a steadfast rule given improved skills of surgeons with laparoscopic surgery and the understanding that surgery delayed to a different admission could potentially lead to worse complications.

A recent study from Italy seems to confirm these data. Patients ($n = 316$) were enrolled in a prospective study³⁸ to assess the benefit of immediate cholecystectomy during the index admission or delayed surgery after at least 4 weeks. As with the other studies, the complication profiles were no different between the two groups; however, the subgroup analysis within the early intervention group showed that immediate surgery on admission or early surgery within 48 hours was associated with shorter operative time, similar conversion and complication rates, and shorter hospital stay. Within the delayed group, 26% required rehospitalization and 37% required urgent reevaluation prior to planned surgery.

Percutaneous Cholecystostomy. In the otherwise healthy patient with AC, laparoscopic cholecystectomy should be considered the therapy of choice during the index hospitalization. However, in the elderly patient with poor performance status, multiple comorbidities, or for the extremely ill patient in the intensive care unit, the underlying medical status may impact increased perioperative risk and therefore preclude surgical intervention. Percutaneous cholecystostomy (PC) may be employed as a bridge or final therapy in such patients. This procedure was first described in the 1980s by Radder et al.³⁹ and involves the placement of a percutaneous transhepatic drain into the gallbladder (Fig. 61-7). The transhepatic approach has remained the method of choice to reduce intraperitoneal bile leak in case of tube dislodgement. Use of this approach has grown over 500% since 1994, along with the field of interventional radiology.⁴⁰ Typically, rapid patient improvement is seen following decompression in combination with antibiotics tailored to bacterial isolates. In most patients, an interval cholecystectomy will be performed 6 weeks or more after the drain is placed. Removing the drain alone is usually not sufficient, as the cystic duct obstruction is typically still present. If Bile is draining from the catheter, then it may be possible to remove the catheter after 6 weeks without removing the gallbladder in patients with questionable fitness for surgery.

Acalculous Cholecystitis

Acute acalculous cholecystitis (AAC) represents 12% of all cases of AC with the incidence being significantly higher in intensive care unit patients.⁴¹ AAC is associated with increased bile stasis and therefore decreased gallbladder emptying, which typically occurs in the setting of severe illness with multiple contributing mediators, such as the inflammatory response, total parenteral nutrition, and high-dose narcotics. The diagnosis of ACC requires a high index of clinical suspicion, as patients are often critically ill and unable to communicate symptoms. The potential consequences of late diagnosis are considerable, with gallbladder ischemia and progression to gangrene and eventual perforation resulting in a mortality rate of up to 30%.⁴² Diagnosis may be made using bedside ultrasonography following similar criteria as used for acute calculous cholecystitis, with the exception of lack of calculi. The sensitivity of US in this setting ranges from 50% to 100% with a specificity of 90% to 94%. HIDA scan with morphine amplification can be used to increase bile secretory pressure and allow bile to reflux through a contracted gallbladder neck, thereby decreasing false-positive rates, providing sensitivity

rates of 67% to 100% and specificity rates of 69% to 100%.⁴¹

US remains the initial test of choice, as it is relatively inexpensive, and may be performed at the bedside in the ICU. However, a negative US in a patient with a high clinical suspicion for AAC may benefit from a HIDA scan to improve diagnostic yield.⁴³ Treatment of AAC is either a cholecystectomy in the stable patient or more likely, PC tube placement in the critically ill, unstable patient.

Figure 61-7. CT guided placement of a 10-French cholecystostomy tube for acute cholecystitis in a nonoperative patient. Note transhepatic (across the liver) placement. These tubes may be placed using US or CT guidance. (Image courtesy of Aarti Sekhar, MD and David Schuster, MD, Emory University Department of Radiology.)

Chronic Cholecystitis

In most patients (>90%), gallstones are the causative factor of chronic cholecystitis and lead to recurrent episodes of cystic duct obstruction manifesting as recurrent biliary colic. These recurrent attacks can lead to scarring and a nonfunctioning, noncontracting gallbladder. A patient with chronic cholecystitis present similarly to those with symptomatic cholelithiasis (i.e., biliary colic) and it is often difficult to distinguish between the two conditions. Diagnosis is accomplished with a US documenting gallstones in the setting of recurrent episodes of RUQ abdominal pain. Patients may exhibit atypical symptoms or a clinician may desire confirmation of a causal relationship to the calculi seen on US, and a HIDA scan may be useful in this situation.²⁸ The treatment for chronic cholecystitis is cholecystectomy.

Gallstone Pancreatitis

Gallstone pancreatitis develops as a result of choledocholithiasis (gallstones that have migrated into the CBD). Stone impaction at the distal CBD near the Ampulla of Vater, where the CBD and pancreatic duct join, may interfere with the flow of exocrine pancreatic secretions resulting in reflux into the pancreatic duct with subsequent autolysis secondary to release of digestive enzymes. It is the second most common cause of pancreatitis after alcohol abuse. The clinical diagnosis of pancreatitis is made by the constellation of upper abdominal pain, serum amylase or lipase >3 times the upper level of normal, and/or imaging studies demonstrating acute inflammation of the pancreas, although imaging is not generally required.⁴⁴

Treatment for pancreatitis is dependent on the severity of the local and systemic response and beyond the scope of this chapter. However, the underlying cause, the lodged stone, must be addressed. Recent guidelines from the International Association of Pancreatology (IAP),⁴⁴ suggest that the majority of stones will pass by themselves, and only if there is evidence of cholangitis (see below under *cholangitis*) should endoscopic retrograde cholangiopancreatography (ERCP) be performed for stone extraction. Regardless of the need for stone extraction, the gallbladder should be removed to prevent further episodes of pancreatitis.

The timing of the cholecystectomy in the setting of gallstone pancreatitis is controversial. It was previously thought that given the acute inflammation, the risk of injury to the CBD or other structures was too high for immediate surgery and an interval cholecystectomy (4 to 8 weeks from the initial admission) was indicated. Evidence now supports early intervention with cholecystectomy being performed during the index admission.^{45,46}

CHOLECYSTECTOMY

Historical Perspectives

Laparoscopic cholecystectomy is the most common gastrointestinal surgical procedure performed in the United States, with more than 750,000 procedures performed yearly. Carl Langenbuch was the first to describe the open cholecystectomy in Germany in 1882. A century later, laparoscopic cholecystectomy was introduced and has since become the preferred method for removal of the gallbladder with over 90% of elective procedures and 70% of urgent cholecystectomies being performed laparoscopically.²⁵

True contraindications to the laparoscopic approach to cholecystectomy, include (i) patient inability to tolerate pneumoperitoneum, (ii) bleeding diatheses, and (iii) decompensated cirrhosis, given the risk of fracturing of the liver and bleeding.²² Patients at higher risk for complications following the laparoscopic approach are those with AC, morbid obesity, previous upper abdominal surgery, and well-compensated cirrhosis.

Technique

The procedure traditionally is performed using four ports. The abdomen is typically entered near the umbilicus and the abdomen is insufflated to 15 mm Hg. Three further operating ports are placed under direct visualization: two 5-mm ports in the RUQ subcostally in a position to grasp the fundus of the gallbladder and retract it cephalad and another in a position to grasp the infundibulum (often in the anterior axillary and midclavicular lines, respectively), and a third 5-mm trocar or 10/12-mm trocar is placed in the subxiphoid/midepigastirc region (Fig. 61-8).

The fundus and infundibulum are grasped to retract the gallbladder cephalad exposing the cystic duct and the triangle of Calot (defined by the liver edge, cystic duct, and common hepatic duct), which holds the cystic artery (Fig. 61-8). The dissection of the lymphatic and fatty tissue within the triangle should allow for visualization of two distinct structures entering the gallbladder (the cystic artery and cystic duct) creating what is known as the *critical view*. The cystic duct and artery are fully encircled and individually controlled with two surgical clips placed toward the porta hepatis and one toward the gallbladder and then divided. The peritoneum surrounding the gallbladder is then incised, and using the two 5-mm RUQ ports, the gallbladder is maximally retracted in order to develop the adventitial plane between the gallbladder and Glisson capsule (Fig. 61-9). The gallbladder is then removed off the liver from the infundibulum toward the fundus. Hemostasis within the gallbladder fossa is assured and the gallbladder is extracted through the umbilical port, which may need to be enlarged in the setting of significant calculi, within an impermeable plastic bag, which decreases the risk of infection at the site of removal. This is especially true if the gallbladder is acutely inflamed, gangrenous, or perforated as the risk of infection at the extraction site is increased.

Figure 61-8. A: Trocar placement for laparoscopic cholecystectomy. The laparoscope is placed through a 10-mm port just above the umbilicus. Additional ports are placed in the epigastrium, subcostally in the midclavicular, and near the anterior axillary lines. B: The “critical view” of safety. The triangle of Calot is dissected free of all tissue except for the cystic duct and artery, and the base of the liver bed is exposed. When this view is achieved, the two structures entering the gallbladder can only be the cystic duct and artery. Visualization of the common bile duct is not necessary.

If the anatomy is unclear, a cholangiogram may be useful and can be performed laparoscopically via access of the gallbladder infundibulum or proximal cystic duct. A cholangiogram is performed by ligating the cystic duct or gallbladder proximally and incising the anterior surface of the gallbladder

infundibulum or proximal cystic duct for placement of a cholangiocatheter. At this point, a radio-opaque contrast agent is injected, and under fluoroscopy the biliary ductal anatomy is defined. Newer techniques of fluorescent-assisted cholangiogram using systemically injected near-infrared dyes, such as indocyanine green or methylene blue, may assist in identification of the critical structures without requiring intraoperative catheter placement or ionizing radiation exposure making the procedure less technically demanding.⁴⁷

Laparoscopic cholecystectomy in the elective setting for symptomatic cholelithiasis, or as an interval operation in the setting of AC, can often be performed in the outpatient setting. Factors that may influence admission include starting the operation later in the day, uncontrolled pain or nausea, and longer operative time (greater than 1 hour).⁴⁸

Other Approaches

As practitioners and patients have become more exposed and familiar with the laparoscopic treatment of various surgical conditions, desire for even more minimally invasive, and to a certain degree cosmetic approach has increased. This led to the development of the single-incision approach to laparoscopic cholecystectomy (SILS). This is performed by placing a multiport access device through the umbilicus and inserting various instruments through the single port in order to dissect the critical structures and the gallbladder. The safety of SILS in elective cholecystectomies has been proven in various clinical trials.^{49,50} The proponents of SILS espouse the cosmetic appeal, although this metric was not supported in a Cochrane review.⁵⁰ Detractors point to the increased operative time and increased hernia rates.⁵¹

Robotic SILS was developed to improve upon the limitations of standard SILS (reduced visualization and limited traction). The intuitive computer software assists in triangulation of the arms through the single umbilical port and due to proprietary port design (Fig. 61-10), the issue of instrument interference is decreased. This approach, however, may significantly increase the overall cost to the patient and healthcare system with no proven benefit to date in terms of outcomes when compared to conventional laparoscopy. Nonetheless, given the new technology it is still early in the experience and further studies are required to truly determine the niche, if any, for robotic and SILS cholecystectomies.⁵²⁻⁵⁴

Open cholecystectomy has been relegated to a relative rare operation since the introduction and wide spread acceptance of laparoscopic surgery. The open technique is still employed in certain clinical settings, such as (i) the need for a potential second procedure, like concurrent CBD procedure, (ii) known complicated anatomy, or (iii) need for conversion from a laparoscopic procedure to an open procedure due to inability to identify anatomy or unexpected findings in approximately 10% to 15% of planned operations.⁵⁵ Open cholecystectomy can be performed through either an upper midline or right subcostal (Kocher) incision. Unlike laparoscopic cholecystectomy, dissection often begins at the fundus and proceeds in a retrograde, dome-down fashion toward Calot triangle with identification of the cystic artery and duct at the gallbladder neck.

Serious complications of laparoscopic or open cholecystectomy are rare and the associated mortality rate is <0.3%. The most severe complication of cholecystectomy is a biliary tract injury. The incidence of bile duct injury following laparoscopic cholecystectomy is between 0.3% and 0.6% (vs. 0.2% and 0.3%, historically for open surgery). Major vascular injuries, especially to the right hepatic artery, may occur in association with biliary injuries due to their close anatomic relationship. Otherwise, vascular injuries to hepatic vessels and other major causes of bleeding are rare.

Figure 61-9. A: The peritoneum overlying the cystic duct–gallbladder junction is opened with blunt dissection. B: The cystic duct is isolated. C: The cystic duct is clipped proximal and distal and divided with the hook scissors. D: The cystic artery is dissected, clipped, and divided. E: The gallbladder is dissected from the liver by scoring the serosa with electrocautery.

Spillage of stones into the peritoneal cavity during laparoscopic cholecystectomy occurs in 5% to 40% of cases. Intra-abdominal abscess, subcutaneous abscess, and fistulization of stones through the abdominal wall have all been described and therefore every attempt should be made to remove spilled stones. Large stones or massive spills should be removed as best possible to prevent delayed complications, but mandatory laparotomy does not appear necessary.⁵⁶

Figure 61-10. (A) Single port robotic (umbilical placement) and (B) conventional port positioning for robotic cholecystectomy: red, green, and yellow = robot arms (arms 1, 2, and 3, respectively); blue = camera port; white = assistant port if needed.

Special Considerations

Gallbladder Cancer

A gallbladder containing an unsuspected cancer is removed in 0.2% to 3% of all laparoscopic cholecystectomies.⁵⁷ If cancer is suspected preoperatively (30% of cases), the gallbladder should be extracted in an impermeable bag to reduce the risk of seeding the peritoneum and/or port sites. If a gallbladder cancer is discovered, additional hepatic resection may be required and appropriate referral to a hepatobiliary specialist is indicated. Of note, severe AC may present in a similar manner on imaging as a gallbladder cancer and complicate management decisions as to whether an upfront en-bloc resection should be performed (Fig. 61-11).

Cholecystoenteric Fistulae

Fistulization occurs in approximately 1% to 2% of all patients undergoing a cholecystectomy. The most common site of fistulization is to the duodenum and colon.⁵⁸ A fistula develops secondary to decompression of the gallbladder into the adjacent bowel loop during an episode of AC. Complications of a cholecystoenteric fistula are rare, but a large gallstone may pass into the bowel and cause a mechanical bowel obstruction, usually distally in areas of narrow caliber, such as the ileocolic valve or sigmoid colon. This obstruction is known as a *gallstone ileus*. If this complication occurs, the initial management involves removal of the gallstone through an enterotomy with possible bowel resection. Decision to proceed with removal of the biliary-enteric fistula and cholecystectomy at the time of operation rests on surgical judgment, taking patient fitness and degree of tissue inflammation into account.⁵⁹ Staging the operative repair of the fistula and cholecystectomy to a later date should be considered. An association between the presence of a cholecystoenteric fistula and gallbladder cancer has been suggested, therefore a certain degree of clinical suspicion for cancer is warranted in this scenario.

(Adapted from Collins C, Maguire D, Ireland A, et al. A prospective study of common bile duct calculi in patients undergoing laparoscopic cholecystectomy: natural history of choledocholithiasis revisited. *Ann Surg* 2004;239(1):28–33.)

Cholecystitis During Pregnancy

After appendicitis, biliary disease is the second most common gastrointestinal ailment requiring surgical consideration during pregnancy.⁶⁰ The development of biliary disease in pregnancy appears to be secondary to the hormonal changes that occur during pregnancy which both increase the cholesterol secretion in bile and decrease bile acid secretion and gallbladder contractility. Gallstones develop in up to 3% of pregnant women with gallbladder sludge seen in up to 30% of cases. Medical therapy alone is associated with a failure rate that varies depending on the trimester of pregnancy (92% for first trimester, 69% for second trimester, and 44% for third trimester).⁶¹ Fetal demise unfortunately occurs in 12% of nonoperatively treated woman with AC, and is significantly higher in women who develop gallstone pancreatitis. The risk of miscarriage after an operative intervention for AC is between 2.2% and 5.6%.⁶² There are no prospective studies evaluating cholecystectomy during pregnancy, but evidence-based guidelines suggest that laparoscopic surgery is safe in any trimester, although trocar positioning may need to be adjusted.⁶³

CHOLEDOCHOLITHIASIS

Overview

Choledocholithiasis, defined as the presence of stones in the extrahepatic biliary tree, is a routine, yet to a certain degree diagnostic and therapeutically challenging, gastrointestinal illness encountered by the practicing general surgeon. The last few decades have seen considerable advancements in both the diagnostic modalities and treatment approaches available in the management of choledocholithiasis or as more commonly referred to CBD stones. In this section, we will discuss the clinical presentation and management of CBD stones.

Classification and Etiology

CBD stones are typically classified as primary or secondary stones. Primary CBD stones originate within the bile duct and are more commonly seen in patients from Southeast Asian countries. Primary CBD stones can also develop in conditions associated with bile stasis, such as: (i) benign biliary strictures, (ii) bile duct cysts (choledochal cysts), or (iii) sphincter of Oddi dysfunction. These stones are characteristically pigmented stones, which form *de novo* as a result of bactericidal action on calcium bilirubinate, thus producing a soft brown-pigmented stone.^{64,65}

Secondary stones originate from the gallbladder and migrate into the bile duct. They are the most common type of CBD stone accounting for approximately 85% of CBD stones seen in the United States

and Western countries. The majority (75%) of these stones are cholesterol stones with only a minority being black-pigmented stones.^{66,67} It is estimated that approximately 10% to 15% of patients with symptomatic gallstones will have CBD stones and the vast majority of patients with secondary CBD stones will have gallstones.^{68,69}

Clinical Presentation

7 CBD stones, similar to gallbladder stones, can have an asymptomatic course and pass spontaneously into the duodenum without clinical consequence.⁶⁹ The exact incidence and frequency in which this occurs is unknown. In nonjaundiced patients with nondilated bile ducts on US, the incidence of CBD stones at the time of cholecystectomy is approximately 5% with one-third of these patients passing the stone(s) spontaneously (Fig. 61-12).

When symptomatic, the presentation of CBD stones can vary between mild biliary colic to fulminant sepsis from acute cholangitis, biliary pancreatitis, or hepatic abscesses. Biliary colic is the most common presentation and it is characterized by intermittent RUQ abdominal pain due to the increased pressure that develops within the obstructed bile duct. These episodes can also be associated with jaundice and in the absence of a superimposed bile infection this process can occur sporadically over time as the stone intermittently obstructs the flow of bile, resulting in development of acute ascending cholangitis. Biliary pancreatitis is the second most common presentation of CBD stone disease.

Predictors of Common Bile Duct Stones

There is no single biochemical or radiologic test that accurately predicts the presence of CBD stones. Numerous studies have assessed the predictive value of serum liver biochemical tests (total bilirubin, alkaline phosphatase, γ-glutamyl transpeptidase, alanine aminotransferase, and aspartate aminotransferase) and the utility of transabdominal US in predicting the diagnosis of CBD stones. Although liver biochemical tests have a strong negative predictive value of 97%, they only have a positive predictive value of 15% to 50% when they are abnormal in patients with suspected CBD stones.^{70,71} Transabdominal US is a valuable test in diagnosing gallbladder stones however, its utility in detecting CBD stones is poor with a sensitivity of 22% to 55%.⁷² Therefore, a thorough history and physical examination, in conjunction with the appropriate biochemical and imaging studies, are required when clinical suspicion for CBD stones exists.

Table 61-4 A Proposed Strategy to Assign Risk of Choledocholithiasis in Patients with Symptomatic Cholelithiasis Based on Clinical Predictors

Predictors of choledocholithiasis	
Very strong CBD stone on transabdominal US Clinical ascending cholangitis Bilirubin >4 mg/dL	
Strong Dilated CBD on US (>6 mm with gallbladder in situ) Bilirubin level 1.8–4 mg/dL	
Moderate Abnormal liver biochemical test other than bilirubin Age older than 55 yrs Clinical gallstone pancreatitis	
Assigning a likelihood of choledocholithiasis based on clinical predictors	
Presence of any very strong predictor	High
Presence of both strong predictors	High
No predictors present	Low
All other patients	Intermediate

CBD, Common bile duct.
Adapted from Maple JT, Ben-Menachem T, Anderson MA, et al. The role of endoscopy in the evaluation of suspected choledocholithiasis. *Gastrointest Endosc*, 2010. 71(1): p. 1–9.

Numerous prognostic nomograms, formulas, and algorithms have been developed to assist the clinician in establishing the diagnosis of CBD stones.⁷² The American Society for Gastrointestinal

Endoscopy proposed a risk-stratification scheme based on common predictive factors previously identified (Table 61-4).⁷² Using this scheme, patients can be categorized into low (<10%), intermediate (10% to 50%), or high (>50%) probability of choledocholithiasis. This scheme has subsequently been validated in a large multi-institutional series of patients with suspected choledocholithiasis.⁷³

Diagnostic Studies

Biochemical Liver Profile

Serum chemistry analysis of liver enzymes (AST and ALT) as well as total bilirubin and alkaline phosphatase levels are routinely performed in patients being evaluated for calculous biliary pathology. Elevated total bilirubin (>4 mg/dL) and alkaline phosphatase levels have typically been correlated with the presence of CBD stones. In addition, elevated gamma-glutamyltransferase levels, although not routinely obtained, has been correlated with the presence of CBD stones with a sensitivity of 85%.

Ultrasonography

Transabdominal US (Fig. 61-13A) plays a critical role in the diagnosis of gallbladder stones and has the advantages of being noninvasive, widely available, and inexpensive. Unfortunately, studies have shown that US is limited in its ability to reliably detect CBD stones (sensitivity of 15% to 30%); primarily due to its inability to adequately assess the distal CBD because of overlying bowel in this region. The value of US in the assessment of CBD stones is in its ability to detect a dilated CBD. A normal CBD diameter is 3 to 6 mm although a mild increase in CBD diameter with increasing age can be seen.⁷⁴ A CBD diameter ≥ 8 mm is considered abnormal and suggestive of CBD stones in a jaundiced patient with gallstones. The sensitivity in detecting a dilated CBD on US is 77% to 87% with a negative predictive value of 95% when a normal CBD is seen.⁷¹ It is important to note that CBD stones can still be present in the absence of a dilated CBD.

Endoscopic ultrasound (EUS) is a semi-invasive procedure that can assess for distal CBD stones with a sensitivity and specificity of 88% to 94% and 94% to 95%, respectively.^{75,76} EUS is superior to other invasive diagnostic studies in its ability to detect small (<5 mm) CBD stones and is associated with an extremely low complication rate (0.1% to 0.3%).⁷⁷ Certain treatment algorithms are recommending an EUS-first approach prior to ERCP in patients at intermediate risk of CBD stones, when the diagnosis of choledocholithiasis is unclear, or in patients with severe gallstone pancreatitis. If no stones are seen on EUS, an ERCP can be avoided. Use of this approach will depend on the local expertise and availability of this technology and the increased clinical and financial costs must be taken into consideration.

Laparoscopic intraoperative US using a high-frequency (7.5- to 10- MHz) probe allows for successful evaluation of the CBD in 88% to 100% of cases with a sensitivity of detecting CBD stones of 71% to 100%.⁷⁸ In addition, laparoscopic US, similar to EUS, allows for the adequate evaluation of the distal bile duct for stones. It is important to note that all types of US modalities are limited by the inability to provide a therapeutic intervention.

Computed Tomography

Overall helical CT (Fig. 61-13B) has shown a slighter better sensitivity (65% to 88%) and specificity (73% to 97%) rate in detecting CBD stones when compared to transabdominal US. This comes at an increased cost to the healthcare system and potentially unnecessary radiation exposure. The utility in CT is its ability to assess for other conditions that may have similar presenting symptoms as CBD stones. CT cholangiography has not been widely adopted across centers and therefore is still in evolution.

Magnetic Resonance Imaging

Magnetic resonance cholangiopancreatography (MRCP) has proven to be a useful adjunct in the diagnosis of CBD stones (Fig. 61-13C). MRCP has the advantage of being noninvasive and providing detailed biliary anatomy. This comes at an increased cost as well as an inability to provide any therapeutic intervention. The accuracy of detecting CBD stones with MRCP is between 93% and 100% and it has a sensitivity of 85% to 92% and specificity of 97%.^{79,80} Recent data suggest that MRCP may not be that sensitive in detecting small CBD stones, as evidenced by a sensitivity of 33% to 70% in patients with CBD stones <6 mm.⁸¹ Selective use of MRCP in patients at low and intermediate risk of CBD stones can identify patients who may benefit from an endoscopic or intraoperative bile duct exploration.

Cholangiography

8 The gold standard in the diagnosis of CBD stones has been direct cholangiography. This traditionally has been accomplished by invasive methods such as ERCP, percutaneous transhepatic cholangiography (PTC), and intraoperative cholangiography (IOC).

ERCP is currently the most routinely used invasive method in the assessment of patients with presumed CBD stones (Fig. 61-13D). ERCP typically involves an endoscopic sphincterotomy followed by catheter access of the biliary tree for cholangiogram. ERCP sensitivity has been reported to be between 89% and 93% with a specificity of 100%.^{82,83} The primary advantage of ERCP is that it allows for therapeutic intervention if stones are identified. However, since ERCP is an invasive procedure it is associated with increased morbidity. Complications that can develop after ERCP are pancreatitis (1.3% to 6.7%), ascending biliary infection (0.6% to 5%), hemorrhage (0.3% to 2%), and perforation (0.1% to 1.1%).⁷² Due to its invasiveness and associated complications, ERCP should be reserved for those patients at high risk of having CBD stones.

Figure 61-13. CBD stones are identified (*white arrow*) on ultrasonography (A), computed tomography (B), MRCP (C), and ERCP (D).

PTC is comparable to ERCP in terms of success rate (>90% with dilated intrahepatic bile ducts) and complication rate (~5%); however, it is typically used in cases in which ERCP was unsuccessful or aberrant gastroduodenal anatomy is present.

IOC, which can be accomplished laparoscopically or open, is primarily performed as adjunct to cholecystectomy (Fig. 61-12). IOC has an overall success rate for detecting CBD stones of >95% with a sensitivity and specificity of 59% to 100% and 93% to 100%, respectively.⁷² To improve upon its accuracy, adequate filling of the intrahepatic bile ducts as well as flow of contrast into the duodenum should be identified and appropriately documented. CBD stones identified on IOC can then be addressed immediately with a laparoscopic or open CBD exploration or postoperatively via ERCP (discussed further below). Traditionally, the three primary purposes of performing an IOC were to define biliary ductal anatomy, identify CBD stones, and serve as an educational tool. There is still considerable debate on whether or not IOC, more specifically laparoscopic IOC, should be performed routinely versus selectively during laparoscopic cholecystectomy.⁸⁴ Advocates argue that asymptomatic CBD stones can be identified and biliary injuries prevented by performing routine IOC. Proponents of selective IOC

argue that patients should be risk-stratified and only those patients at considerable risk should undergo IOC.

Management

Before the laparoscopic era, IOC was routinely performed and identification of CBD stones was managed immediately with open CBD exploration and T-tube biliary drainage. In the current era, patients should be appropriately risk-stratified by a thorough history and physical examination with appropriate biochemical liver profile and imaging adjuncts to assess for possible CBD stones. As described above, there are many diagnostic options available to the practicing surgeon to assess for CBD stones and once the diagnosis of CBD stones is established, many options, from a therapeutic standpoint, are also available to the treating surgeon. These options include (i) endoscopic, (ii) percutaneous, (iii) laparoscopic, and (iv) open approaches or a combination of any of these techniques.

The choice of the best diagnostic test and ultimate therapeutic intervention is dictated in great part by the local expertise of the radiologist, gastroenterologist, interventional radiologist, and surgeon at the treating institution (Algorithm 61-1). Hence, no single standardized approach to the diagnosis and management of CBD stones has been established. Nonetheless, patients at low to intermediate risk of CBD stones can be evaluated by less invasive diagnostic methods preoperatively (MRCP or EUS) or intraoperatively with IOC. Patients at high risk of stones should undergo preoperative ERCP. The clinical scenario in which the CBD stones present, asymptomatic (incidental stone) versus symptomatic (cholangitis, biliary pancreatitis, or jaundice), must be put into context and incorporated into the treatment decision plan.

Algorithm 61-1. Algorithm for the management of common bile duct stones.

Endoscopic Approach

9 ERCP with endoscopic sphincterotomy allows for the diagnosis and treatment of CBD stones. ERCP with stone extraction is effective in removing stones in 85% to 95% of cases. Stone extraction is typically accomplished with either a balloon catheter or stone basket. Additional techniques, such as mechanical lithotripsy, extracorporeal shock-wave lithotripsy, or intracorporeal lithotripsy with laser or electrohydraulic probes have been used to manage large stones (>15 mm), multiple stones, hard stones, and/or intrahepatic stones.

Circumstances in which ERCP with sphincterotomy should be considered as the initial therapeutic intervention are (i) acute cholangitis secondary to distal CBD stone, (ii) gallstone pancreatitis with biliary obstruction, (iii) in frail medically unfit patients, and (iv) in patients who require cholecystectomy whom are found to be at high risk or have CBD stones. Additionally, it is recommended that preoperative ERCP be undertaken if expertise in laparoscopic CBD exploration is not

available. Preoperative ERCP will allow the treating clinician to identify circumstances (i.e., large stones, impacted stones, duodenal diverticula, aberrant gastroduodenal anatomy, or bile duct stricture) in which the patient may not be amenable to endoscopic stone extraction and thus would require either percutaneous or surgical biliary drainage depending on the available expertise at the treating institution.

An alternative approach for patients at low or intermediate risk of CBD stones would be to perform an IOC at the time of cholecystectomy with plans to perform an ERCP either intraoperatively or postoperatively, if indicated. In the latter situation, this would require another anesthetic intervention and the surgeon runs the risk that complete bile duct clearance is not achieved endoscopically and additional procedures would be required.

Percutaneous Approach

From a therapeutic standpoint, simple percutaneous biliary drainage for decompression of an obstructed biliary tree can be performed safely and efficiently with minimal difficulty. However, percutaneous transhepatic CBD stone removal is more labor intensive and normally requires multiple sessions after initial access of the biliary tree. Maturation (at least 7 days) of the transhepatic fistula from the skin to the bile duct is required prior to attempting percutaneous stone extraction with either balloon catheter or stone basket. In addition, various procedures, such as mechanical lithotripsy, electrohydraulic lithotripsy, and extracorporeal shock-wave lithotripsy can then be performed via a percutaneous route once a mature transhepatic fistula has been established.

Laparoscopic Approach

Concomitant laparoscopic common bile duct exploration (LCBDE) at the time of laparoscopic cholecystectomy is a method that allows for the complete management of secondary CBD stones and gallstones in one setting. The main advantage of this approach is that all of the calculous biliary pathology is addressed with one intervention and under one anesthetic procedure. Studies have shown that the success rate of this concomitant approach is approximately 94% to 97%, which is similar to outcomes seen with endoscopic clearance.^{85,86} The morbidity of a LCBDE (7%) compares favorably to ERCP. However, LCBDE has yet to gain widespread use, due in great part to the lack of adaptation and expertise across institutions. LCBDE is ideal for patients with CBD stones incidentally identified at the time of IOC or those suspected to be at high risk of having CBD stones. LCBDE can be performed via a transcystic, transcholecystic, or choledochotomy technique. Cystic and CBD diameter and stone size, location, and number need to be considered when determining the appropriate LCBDE technique.

Laparoscopic transcystic CBDE is the preferred technique and allows for the extraction of small (< 1 cm) CBD stones if the diameter and quality of the cystic duct allows. A tortuous or low-inserting cystic duct, large (> 1 cm) stones, and/or common hepatic or intrahepatic stones are relative contraindications to this technique. This technique avoids the need for a choledochotomy and thus potential need for a T-tube. The transcystic approach involves placement of a guide wire into the CBD through the cystic ductotomy made for the IOC. With the guide wire in place, a cholangiocatheter can be advanced into the CBD, which is then saline irrigated in attempt to flush small stones out of the bile duct under fluoroscopic guidance. An adjunct to this maneuver is to dilate the major papilla with a Fogarty balloon catheter and/or administer intravenous glucagon prior to flushing the CBD in order to facilitate the passage of stones. A 3-mm choledochoscope can be passed into the CBD for direct visualization and stone extraction can be accomplished with the use of a basket. An adjunct to this technique is to dilate the cystic duct prior to stone extraction. These techniques can also be applied to the transcholecystic approach, which involves making an incision in the body of the gallbladder. At the completion of either of these approaches, the cystic duct can be easily closed as it is typically done during laparoscopic cholecystectomy, and biliary drainage with a T-tube is not necessary.

An alternative laparoscopic approach is to perform a laparoscopic choledochotomy. The advantage to this approach is that multiple stones, larger stones (> 1 cm), or common hepatic or intrahepatic stones can be removed. In this approach, an anterior longitudinal incision on the CBD below the cystic duct is made to allow for adequate access but also to avoid unwanted injury to the arterial supply of the bile duct. Similar techniques of CBDE, discussed previously, can then be undertaken to clear the CBD of stones. The disadvantage of this approach is that advanced laparoscopic biliary skills are required and conventionally, the choledochotomy is closed over a T-tube. The potential benefits of leaving a T-tube is that it allows for the postoperative decompression of the biliary tree, potentially minimizes bile strictures, and allows for access to the biliary tree postoperatively in case of retained stones⁸⁷; this approach has been associated with a higher morbidity rate when compared to the transcystic approach.

The increased complication rate is primarily attributed to the placement of the T-tube, and is due to (i) bile leakage, (ii) wound issues at T-tube insertion site, (iii) dislodgement or displacement of T-tube leading to biliary obstruction, and (iv) persistent biliary fistula.⁸⁸ Alternative biliary drainage approaches, such as intrabiliary stenting, endoscopic nasobiliary drainage, percutaneous transhepatic biliary drainage, C-tube, and J-tube drainage via the cystic duct after laparoscopic choledochotomy, have been investigated and have shown promising results.⁸⁷ Moreover, recent data suggest that routine biliary drainage with a T-tube is not indicated and primary closure of the CBD is superior to drainage with a T-tube in regard to postoperative complications and biliary-specific complications.⁸⁷

Open Approach

In the previous era of open cholecystectomies, open CBD exploration was routinely performed and was the standard treatment for CBD stones. It was associated with a low morbidity rate and low stone retention rate (1% to 3%). In the current era of advanced endoscopic, percutaneous, and laparoscopic approaches, open CBD exploration is infrequently performed. However, when other approaches fail, open CBD exploration may be necessary. This technique starts with a wide Kocher maneuver to allow for exposure and palpation of the entire bile duct. The choledochotomy is similar to the one made laparoscopically and the methods of stone extraction are also similar with the added benefit that digital manipulation is possible. A 12-French T-tube is usually placed and secured with interrupted sutures (4-0 absorbable sutures). Completion cholangiography is mandatory to assess for CBD clearance and for leakage around the T-tube. The T-tube is left to gravity bag until postoperative days 3 to 7 when a T-tube cholangiogram is performed and if no obstruction is present the tube can be clamped and eventually pulled after 4 to 6 weeks once the tract has matured. If retained stones are identified, the biliary tree can be accessed percutaneously via the T-tube, once the tract has matured, and the stones can be removed.

Certain patients with impacted stones at the ampulla or with primary bile duct stones, history of recurrent stones, intrahepatic stones, or a benign distal bile duct stricture may require an open biliary drainage procedure, such as a transduodenal sphincteroplasty or choledochoduodenostomy or Roux-en-Y biliary bypass (i.e., choledochojejunostomy or hepaticojejunostomy) as definitive therapy. The advantage of a choledochoduodenostomy is that endoscopic access to the bile duct is maintained, however if a side-to-side choledochoduodenostomy is performed, the patient is at risk for developing a *sump syndrome* (obstruction of the distal limb of the bile duct with food debris leading to possible obstruction of the anastomosis, cholangitis, and/or pancreatitis). This syndrome is avoided with a Roux-en-Y biliary bypass, however at the cost of losing access to the bile duct endoscopically.

ETIOLOGY OF ACUTE CHOLANGITIS

Table 61-5 Etiologies of Acute Cholangitis

Noniatrogenic
Benign Conditions
Cholelithiasis
Primary
Secondary
Pancreatitis (chronic/acute), including pancreatic pseudocyst
Papillary stenosis
Mirizzi syndrome
Choledochal cysts and Caroli disease
Biliary strictures
Ischemia
Primary sclerosing cholangitis
Recurrent cholelithiasis
Recurrent cholangitis
Other inflammatory conditions
Malignancies
Pancreatic cancer
Cholangiocarcinoma
Duodenal/ampullary cancer
Primary tumor or metastasis to liver, gallbladder, or porta hepatitis
Iatrogenic
Obstructed biliary endoprosthesis
Iatrogenic biliary stricture
Direct surgical trauma
Ischemia-induced stricture
Anastomotic stricture (bilobiliary/bilioenteric anastomosis)

Adapted from *Cameron: Current Surgical Therapy*, 11th ed. 2014.

Specific Conditions

Acute Cholangitis

10 Acute cholangitis can be a morbid condition and thus prompt recognition and initiation of treatment is paramount. Acute cholangitis is defined by bacterial infection of an obstructed biliary ductal system. [Table 61-5](#) lists the various causes of cholangitis. The most common cause for cholangitis is cholelithiasis; however, malignant strictures that have required endoscopic or percutaneous manipulation are becoming a routine cause of acute cholangitis at tertiary referral centers. The spectrum of clinical severity can range from a mild self-limited course to a more severe potentially life-threatening disease characterized by fulminant sepsis with multiorgan dysfunction. The classic triad of RUQ pain, fever, and jaundice, known as Charcot triad, commonly defines the clinical presentation of cholangitis. Development of septic shock and mental status changes in this setting is known as Reynolds pentad.

Acute cholangitis is a clinical diagnosis supported by laboratory and radiographic studies. Elevated bilirubin, alkaline phosphatase, and transaminase levels in conjunction with a leukocytosis are commonly present. Radiographic studies will confirm the presence of an abnormal dilated biliary ductal system.

The management of cholangitis should follow three principles: (1) vigorous resuscitation and hemodynamic support, (2) broad-spectrum antibiotics, and (3) relief of biliary obstruction ([Algorithm 61-2](#)).⁸⁹ The majority (80%) of patients who present with acute cholangitis will improve with fluid resuscitation and administration of antibiotics, and therefore CBDE with biliary decompression can be performed in a more elective and stable environment. Emergent biliary decompression will be required in 20% of patients who do not respond clinically within 12 to 24 hours of initiation of medical management or in patients who present with a toxic clinical picture. Biliary decompression can be achieved either endoscopically or percutaneously. In patients with a perihilar obstruction, strictured biliary-enteric anastomosis, or nonfunctioning percutaneous biliary drainage catheters are best managed via the percutaneous route. If the obstruction is within the distal biliary tree then endoscopic biliary drainage is recommended. This can be accomplished by endoscopic biliary CBDE and stone extraction or by simple biliary decompression with placement of a plastic biliary stent in unstable patients. In the setting in which either percutaneous or endoscopic drainage is not possible or available, then surgical

CBD exploration and biliary drainage with a T-tube is indicated.

Intrahepatic Stones

Intrahepatic stones, or hepatolithiasis, are a form of primary CBD stones that are infrequently encountered in Western countries and are primarily prevalent in Southeast Asian countries. Intrahepatic stones are defined as stones present above the confluence of the left and right hepatic ducts. These stones are primarily brown pigment stones that contain more cholesterol, and less bile acids and bilirubin than extrahepatic stones. The Japanese have classified intrahepatic stones, as *type I* for patients with intrahepatic stones only, *type IE* for patients with intra- and extrahepatic bile duct stones, *type L* for left-sided intrahepatic duct stones, *type R* for right-sided intrahepatic duct stones, and *type C* for caudate stones. *Type I* stones account for approximately 45% to 50% of intrahepatic stones identified in Asian countries,⁹⁰ however in Italy *type I* stones account for approximately 75% of intrahepatic stones.⁹¹ Intrahepatic stones typically occur in the setting of chronic biliary stasis secondary to processes, such as (i) choledochal cysts, (ii) biliary strictures, and (iii) biliary parasites. Interestingly, the majority (70%) of patients with intrahepatic stones do not have concomitant gallbladder stones.

Algorithm 61-2. Management of acute cholangitis. (Adapted from *Cameron: Current Surgical Therapy*. 11th ed. 2014.)

Intrahepatic stones typically present with RUQ or epigastric abdominal pain associated with jaundice and fever. The previously discussed diagnostic modalities (US, CT, MRCP, and endoscopic and percutaneous cholangiogram) have similar advantages and disadvantages when evaluating patients with intrahepatic stones. Ultimately, an endoscopic or percutaneous cholangiogram will be required for complete evaluation. The percutaneous transhepatic approach with placement of biliary drainage catheters is preferred since it allows for direct access to the intrahepatic bile ducts for subsequent therapeutic interventions. With advancements in percutaneous transhepatic techniques, intrahepatic stones can be managed nonsurgically in many cases using similar endoscopic techniques of stone extraction or stone lithotripsy mentioned previously; however, surgery also plays a critical role in the management of intrahepatic stones. If the intrahepatic stone disease is isolated to a single segment or lobe of liver and is associated with significant parenchymal atrophy or biliary strictures, then hepatic

resection of this portion of liver should be considered. If stones occur in the setting of a stricture at the biliary confluence, then a Roux-en-Y hepaticojejunostomy may be warranted.

Chapter 62

Biliary Injuries and Strictures and Sclerosing Cholangitis

Chad G. Ball and Keith D. Lillemoe

Key Points

- 1 Most bile duct injuries or strictures currently occur in association with laparoscopic cholecystectomy, with an overall incidence of 0.3% to 0.7%.
 - 2 Recognition of a bile duct injury during laparoscopic cholecystectomy is uncommon (< 30% of cases), but if recognized, repair as either an end-to-end duct-to-duct anastomosis in very selected cases or hepaticojejunostomy should be performed.
 - 3 Cholangiography, usually performed by a percutaneous transhepatic route, should be performed in all cases to define the proximal biliary anatomy needed for reconstruction and to allow placement of biliary catheters to control the ongoing bile leak.
 - 4 Patients with biliary injuries most commonly present in the early postoperative course, usually with bile leakage. Despite recognition of an ongoing bile leak, urgent return to the operating room should be avoided.
 - 5 The repair of a bile duct injury recognized in the postoperative period requires a hepaticojejunostomy in almost all cases and should be performed with transanastomotic biliary stents.
 - 6 A successful result following repair of a bile duct injury can be expected in 80% to 90% of patients. Return to a normal quality of life is also expected. In the modern era, death associated with either bile duct injury or the operative repair is uncommon, occurring in less than 2% of patients.
 - 7 Percutaneous or balloon dilatation of biliary strictures can lead to successful outcomes in selective patients, although the long-term results generally favor surgical reconstruction.
 - 8 Primary sclerosing cholangitis is an autoimmune disease characterized by intrahepatic and extrahepatic inflammatory strictures of the bile ducts. Patients are at risk for the development of cholangiocarcinoma and/or end-stage liver disease. There is no known specific effective medical therapy for primary sclerosing cholangitis. Primary sclerosing cholangitis has become one of the most common indications for liver transplantation.
 - 9 Bile duct strictures associated with alcoholic chronic pancreatitis are best managed by biliary bypass.
-

Biliary injuries and strictures are among the most difficult challenges that a surgeon faces. Although numerous technologic developments have facilitated diagnosis and management, bile duct injuries and strictures remain a significant clinical problem. If they go unrecognized or are managed improperly, life-threatening early complications such as sepsis and multisystem organ failure or late implications of biliary cirrhosis, portal hypertension, and cholangitis can develop. To avoid these complications, virtually every patient with a bile duct stricture should undergo evaluation and treatment with the goal of relieving the obstruction to bile flow and its associated hepatic injury. Finally, the occurrence of a major bile duct injury during an elective cholecystectomy remains one of the most common indications for charges of medical practice in the United States.

Benign bile duct strictures can have numerous causes ([Table 62-1](#)). Most biliary strictures occur after primary operations on the gallbladder or biliary tree. With the introduction of laparoscopic cholecystectomy, bile duct injuries and associated strictures have been seen with increased frequency. Operative injury to the bile ducts can also occur during nonbiliary operations on the gallbladder or biliary tree or as a result of external penetrating or blunt abdominal trauma. Inflammatory conditions and fibrosis caused by chronic pancreatitis, gallstones in the gallbladder or the bile duct, stenosis of the sphincter of Oddi, or biliary tract infections can also cause benign bile duct strictures. Finally, primary

sclerosing cholangitis, a rare disease of unknown cause, can result in multiple strictures of the intrahepatic and extrahepatic bile ducts. This chapter focuses primarily on postoperative bile duct strictures and primary sclerosing cholangitis.

POSTOPERATIVE BILE DUCT STRICTURES

Pathogenesis

1 Most benign bile duct strictures result from operations in or near the right upper quadrant. More than 80% of strictures occur after injury to the bile ducts during cholecystectomy. The exact incidence of bile duct injury is unknown because many cases may go unreported in the literature. Data suggest that the incidence of bile duct injury during open cholecystectomy is 1 in 500 to 1,000 cases. The incidence of bile duct injury during laparoscopic cholecystectomy is clearly higher. Although a wide range in the incidence of injury can be found in reported series, the most accurate data most likely come from surveys encompassing thousands of patients. These reports reflect the results from a large number of surgeons in both community and teaching hospitals. The results of such series suggest an incidence of bile duct injury during laparoscopic cholecystectomy ranging from 0.3% to 0.7%.¹ Furthermore, the incidence of bile duct injury associated with laparoscopic cholecystectomy does not appear to have diminished in more recent surveys, suggesting that the previously observed increase is not simply the result of a learning curve associated with the laparoscopic technique. Finally, due to the high frequency of laparoscopic cholecystectomy, it is estimated that one in every two or three surgeons will create a bile duct injury during his or her career.

ETIOLOGY

Table 62-1 Causes of Benign Bile Duct Strictures

Injury at Primary Biliary Operations
Laparoscopic cholecystectomy
Open cholecystectomy
Common bile duct exploration
Injury at Other Operative Procedures
Gastrectomy
Hepatic resection
Portacaval shunt
Stricture of a biliary-enteric anastomosis
Blunt or penetrating trauma
Strictures Caused by Inflammatory Conditions
Chronic pancreatitis
Cholelithiasis and choledocholithiasis
Primary sclerosing cholangitis
Stenosis of the sphincter of Oddi
Duodenal ulcer
Crohn disease
Viral infections
Toxic drugs

A number of factors are associated with bile duct injury during either open or laparoscopic cholecystectomy, including acute or chronic inflammation, inadequate exposure, patient obesity, and failure to identify structures before clamping, ligating, or dividing them. More specific causes of bile duct injury also exist. Bleeding from the cystic or hepatic arteries can lead to bile duct injury during attempts to gain hemostasis. The generous application of Ligaclips at either open or laparoscopic cholecystectomy to hilar areas not well visualized can result in placing a clip on or across a bile duct, with resultant injury (Fig. 62-1). Failure to recognize congenital anatomic anomalies of the bile ducts, such as insertion of the right hepatic duct into the cystic duct or a long common wall between the cystic duct and the common bile duct, can also lead to injury (Fig. 62-2). It should also be noted that a significant discussion has ensued regarding the optimal timing of performing a laparoscopic cholecystectomy in the setting of acute inflammation of the gallbladder. Although 30-day postoperative morbidity and mortality rates may remain independent of timing, it is clear that patients who undergo

laparoscopic cholecystectomy beyond 24 hours are more likely to require an open procedure, and sustain significantly longer postoperative and overall lengths of hospital admission (and therefore cost).²

A number of technical factors are associated with laparoscopic cholecystectomy that can also increase the risk of bile duct injury compared with the open procedure. These factors include the use of an end-viewing laparoscope, which alters the surgeon's perspective of the operative field. The issue of visual alignment and perspective has become even more topical with the proliferation of single incision laparoscopic cholecystectomy which is known to be associated with a higher rate of common bile duct injury than the traditional 4-incision laparoscopic technique utilizing an angled scope.³ Excessive cephalad retraction of the gallbladder fundus can cause the cystic duct and common bile duct to become aligned in the same plane. This distortion often results in the classic laparoscopic injury, in which the common bile duct is mistaken for the cystic duct and clipped and divided (Fig. 62-3).⁴ The role of intraoperative cholangiography (IOC) in preventing bile duct injury during laparoscopic cholecystectomy is controversial. Individual series have failed to demonstrate that either performing routine or selective IOC affects the incidence of bile duct injury. Although an initial retrospective nationwide cohort analysis of Medicare patients undergoing laparoscopic cholecystectomy between 1992 and 1999 demonstrated that common bile duct injuries occurred in 0.39% of patients in which IOC was performed versus 0.58% in patients not undergoing IOC (unadjusted relative risk, 1.49; 95% confidence interval 1.42–1.57),⁵ a more recent Medicare-based study (2000 to 2009) analyzing over 92,000 patients undergoing cholecystectomy identified no statistically significant association between IOC and common bile duct injury.⁶ The authors therefore concluded that IOC is not effective as a preventive strategy against common duct injury during cholecystectomy.⁶ Furthermore, the proper interpretation of IOC can minimize the extent of injury. Nevertheless, only 27% of surgeons in the United States perform IOC routinely.⁷ Finally, ample evidence exists to support the conclusion that the experience of the surgeon in performing laparoscopic cholecystectomy can be correlated with the risk of bile duct injury.

Numerous surgical clips can be seen in the area of the stricture. (Reproduced with permission from Lillemoe KD, Pitt HA, Cameron JL. Postoperative bile duct strictures. *Surg Clin North Am* 1990;70:1356–1380.)

Figure 62-2. Operative cholangiogram demonstrating a right lobe segmental bile duct entering the cystic duct (*arrow*). Division of the cystic duct proximal to this insertion can result in a bile leak or obstruction of bile flow from a significant segment of the liver.

Figure 62-3. Classic laparoscopic bile duct injury. The common bile duct is mistaken for the cystic duct and transected. A variable extent of the extrahepatic biliary tree is resected with the gallbladder. The right hepatic artery, in background, is also often injured.

In recent years, there has been a growing understanding of surgeon cognitive factors associated with bile duct injury during laparoscopic cholecystectomy. An analysis examining 252 biliary injuries during laparoscopic cholecystectomy using human error factor and cognitive science techniques found that 97% of injuries were caused by visual-perceptual illusion or inadequate visualization.⁸ Further work from the same group has determined a major explanation for the surgeon's frequent inability to recognize bile duct injury. These bile duct injuries appear to be associated with confirmation bias, which is a propensity to seek cues to confirm a belief and to discount cues that might discount the belief. Although cognitive factors are important for the understanding of the psychological issues associated with bile duct injuries, surgeons must continue to have the appropriate corrective mechanisms in place to minimize the chance of these injuries, including knowledge of anatomy, typical mechanisms of injury, and an appropriate level of suspicion and logic. An example of such a corrective mechanism occurs within the operative technique of laparoscopic cholecystectomy, which defines the "critical view of safety," and therefore helps prevent misidentification and injury of the major bile ducts.⁹ This anatomical-based safety concept can be further developed by including the orientation and relative positions of the multiple structure of interest within adjacent regional anatomy (hepatic artery, sulcus of Rouvier, umbilical fissure, and common bile duct).

The importance of ischemia of the bile duct in the formation of postoperative strictures has been

emphasized. Injury to the hepatic artery at the time of biliary injury during laparoscopic cholecystectomy has been recognized at an increased incidence, as high as 50%, when investigated at the time of presentation.¹⁰ The true impact of an arterial injury however, remains debated. It is clear that the most common site of vasculobiliary injury is the right hepatic artery.¹¹ Damage to this vessel can lead to a higher injury level on the bile duct than the gross observed mechanical injury. Vasculobiliary injuries may also have specific effects on the arteries (pseudoaneurysm with delayed hemorrhage), bile ducts (necrosis, stenosis, cholangitis) and/or liver (necrosis, atrophy) over variable lengths of time.¹¹ Finally, concurrent hepatic artery and portal vein injuries can have catastrophic effects on the liver, including rapid necrosis. A more clinically common cause of ischemia can be unnecessary dissection around the bile duct during cholecystectomy or bile duct anastomosis, which can divide or injure the major arteries of the bile duct that run in the 3-o'clock and 9-o'clock positions.

Another important factor contributing to the formation of biliary strictures is the intense connective tissue response with fibrosis and scarring that can occur after bile duct injury. Experimental studies of bile duct ligation in a canine model have demonstrated immediate and sustained elevation of bile duct pressure and progressive increase in bile duct diameter. Histologic changes at 1 month after ligation have shown that the bile duct wall is thickened, with a reduction of mucosal folds and loss of surface microvilli, associated with a well-defined epithelial degeneration. Biochemical analysis of connective tissue response to ligation showed that collagen synthesis and proline hydroxylase activity is increased within 2 weeks in the obstructed bile duct and is sustained throughout the period of observation. Finally, a marked local inflammatory response can develop in the adjacent tissue in association with bile leakage, which occurs with many bile duct injuries. This inflammation can be further intensified in the face of infection. This inflammation results in fibrosis and scarring in the periductal tissue, further contributing to stricture formation. These factors can be of major importance in bile duct injuries during laparoscopic cholecystectomy, which are frequently associated with bile leaks.

After cholecystectomy and common bile duct exploration, the two most common operations associated with bile duct injury are gastrectomy and hepatic resection. The most common situation resulting in bile duct injury during gastrectomy involves dissection of the pyloric region and the first portion of the duodenum in the face of inflammation from peptic ulcer disease. The injury occurs during mobilization of the duodenum either for creation of a Billroth I gastroduodenostomy or for closure of the duodenal stump. Biliary injury during liver resection is most likely to occur during dissection of the hepatic hilum.

In addition to iatrogenic bile duct injury occurring during cholecystectomy or other operations, bile duct strictures can also occur at biliary anastomoses. Such strictures can occur at a biliary-enteric anastomosis performed for reconstruction after resection for benign or malignant disease of the pancreaticobiliary system, or after end-to-end bile duct anastomosis performed for hepatic transplantation (even in the context of chronic immunosuppressive therapy) or for repair of traumatic injury. Ischemia of the anastomosis caused by excessive skeletonization of the duct in preparation for the anastomosis is an important factor in many such strictures.

Unfortunately, the recurrence of bile duct strictures after an initial attempt at repair is not uncommon and can also account for a number of anastomotic strictures.^{12,13} A number of other factors have been evaluated in patients who have a recurrent bile duct stricture, including the location of the stricture, the length of follow-up, the influence of previous operations, the type of operation performed, the type of sutures used, and the use and duration of postoperative stenting.¹⁴ Previous attempts at repair, performance of a procedure other than choledochojejunostomy or hepaticojejunostomy, and stricture location higher in the biliary tree appear to be associated with a higher incidence of recurrent stricture. Finally, long-term follow-up of a bile duct anastomosis is important because strictures can develop years after the original anastomosis.

Clinical Presentation

2 Most patients with biliary injuries present early after their initial operation ([Algorithm 62-1](#)). After open cholecystectomy, only approximately 10% of postoperative strictures are actually suspected within the first week, but nearly 70% are diagnosed within the first 6 months, and more than 80% are diagnosed within 1 year of surgery. In series reporting bile duct injuries during laparoscopic cholecystectomy, the injury is usually recognized either during the procedure (25% to 30%) or, more commonly, in the early postoperative period.

Patients suspected of having a postoperative bile duct injury within days to weeks of initial operation usually present in one of two ways. One presentation is the progressive elevation of liver function test results, particularly total bilirubin and alkaline phosphatase levels. These changes can often be seen as early as the second or third postoperative day. The second mode of early presentation is with leakage of bile from the injured bile duct. This presentation appears to occur most often in patients presenting with bile duct injuries after laparoscopic cholecystectomy. Bilious drainage from operatively placed drains or through the wound after cholecystectomy is abnormal and represents some form of biliary injury. In patients without drains (including patients in whom the drains have been removed), the bile can leak freely into the peritoneal cavity or it can loculate as a collection. Free accumulation of bile into the peritoneal cavity results in either biliary ascites or bile peritonitis. Similarly, a loculated bile collection can result in sterile biloma ([Fig. 62-4](#)) or in an infected subhepatic or subdiaphragmatic abscess.

Patients with postoperative bile duct strictures who present months to years after the initial operation frequently have evidence of cholangitis. The episodes of cholangitis are often mild and respond to antibiotic therapy. Repetitive episodes usually occur before the definitive diagnosis. Less commonly, patients may present with painless jaundice and no evidence of sepsis. Finally, patients with markedly delayed diagnoses may present with advanced biliary cirrhosis and its complications.

Laboratory Investigation

Liver function tests usually show evidence of cholestasis. In patients with bile leakage, the bilirubin can be normal or minimally elevated because of absorption from the peritoneal cavity. When elevated, serum bilirubin usually ranges from 2 to 6 mg/dL, unless secondary biliary cirrhosis has developed. Serum alkaline phosphatase is usually elevated. Serum aminotransferase levels can be normal or minimally elevated except during episodes of cholangitis. If advanced liver disease exists, hepatic synthetic function can be impaired, with lowered serum albumin and a prolongation of prothrombin time. Serum electrolytes and complete blood count are typically normal unless there is associated biliary sepsis.

Radiologic Examination

The imaging techniques of abdominal ultrasound and computed tomography (CT) play an important initial role in the evaluation of patients with benign postoperative biliary strictures. In patients who present in the early postoperative period with evidence of a bile leak or biliary sepsis, these studies are useful to rule out the presence of intra-abdominal collections that might require drainage (Fig. 62-4). CT and ultrasound are also important in the initial evaluation of the patient presenting with a bile duct stricture months to years after initial operation. Both studies can confirm biliary obstruction by demonstrating a dilated biliary tree. CT is especially useful in identifying the level of obstruction of the extrahepatic bile duct.

In patients suspected of having early postoperative bile duct injury, a radionuclide biliary scan can confirm bile leakage. In patients with postoperative external bile fistula, injection of water-soluble contrast media through the drainage tract (sinography) can often define the site of leakage and the anatomy of the biliary tree.

3 The “gold standard” for evaluation of patients with bile duct strictures is cholangiography. Percutaneous transhepatic cholangiography (PTC) is usually more valuable than endoscopic retrograde cholangiography (ERC) in patients with major bile duct injuries following laparoscopic cholecystectomy. PTC is more useful in that it defines the anatomy of the proximal biliary tree that is to be used in the surgical reconstruction (Fig. 62-5). Furthermore, PTC can be followed by placement of percutaneous transhepatic catheters, which can be useful in decompressing the biliary system both to treat or prevent cholangitis and to control an ongoing bile leak. These catheters can also be of assistance in surgical reconstruction and provide access to the biliary tree for nonoperative dilation. ERC is less

useful than PTC in major bile duct transections during laparoscopic cholecystectomy because the discontinuity of the extrahepatic bile duct usually prevents adequate filling of the proximal biliary tree (Fig. 62-6). Often, ERC can demonstrate a normal-sized distal bile duct up to the site of the stricture without visualization of the proximal biliary system (Fig. 62-7). This finding is frequently the case in patients with injury during laparoscopic cholecystectomy, when the distal bile duct is often clipped and divided. The development of magnetic resonance cholangiopancreatography (MRCP) has provided a noninvasive technique that provides excellent delineation of the biliary anatomy. The quality of these images has led some surgeons to advocate this technique as the initial step in the evaluation of patients with suspected bile duct injuries and may eliminate the need for a diagnostic ERC in many patients. MRCP is especially worth considering if the referral surgeon has a low pretest probability of utilizing transhepatic stents for subsequent reconstructive purposes.

Figure 62-6. A: Endoscopic retrograde cholangiogram showing a relatively normal biliary tree in a patient with a postoperative bile collection (see Fig. 62-5). B: Percutaneous transhepatic cholangiogram of the same patient, showing entire right hepatic posterior lobe segment obstructed as the result of ligation of the segmental duct. The patient had an unrecognized anatomic variant similar to that shown in Figure 62-2.

Preoperative Management

4 The preoperative management of a patient with a postoperative bile duct stricture depends primarily on the timing of the presentation. Patients presenting in the early postoperative period can be septic with either cholangitis or intra-abdominal bile collections. Sepsis must be controlled first with broad-spectrum parenteral antibiotics, percutaneous biliary drainage, and percutaneous or operative drainage of biliary leaks. Once sepsis is controlled, there is no hurry in proceeding with surgical reconstruction of the bile duct stricture. The combination of proximal biliary decompression and external drainage allows most biliary fistulas to be controlled or even to close. The patient can then be discharged home to allow several weeks to elapse for resolution of the inflammation in the periportal region and recovery of overall health.

Figure 62-7. Endoscopic retrograde pancreaticholangiogram showing filling of a normal pancreatic duct (PD). The common bile duct (CBD), however, does not fill beyond the large clip that appears to be placed across the duct. (Reproduced with permission from Lillemoe KD, Pitt HA, Cameron JL. Postoperative bile duct strictures. *Surg Clin North Am* 1990;70:1355–1380.)

The management of a suspected bile duct injury after laparoscopic cholecystectomy presenting with a bile leak deserves special mention. Often, when bile leakage is suspected, the surgeon believes that urgent surgical exploration is necessary. Unfortunately, at laparotomy, the marked inflammation associated with bile spillage and the small decompressed biliary tree that appears retracted high into the porta hepatis make recognition of the injury and repair virtually impossible. In such cases, every attempt should be made to define the biliary anatomy by preoperative cholangiography (PTC or MRCP) and to control the bile leak with percutaneous biliary drainage. In many cases, early operative intervention is not required because the bile collections or ascites can either be drained percutaneously or simply is absorbed from the peritoneal cavity. Delayed reconstruction, aided by percutaneous biliary catheters, then allows optimal surgical results.¹⁴

In patients who present with a biliary stricture remote from the initial operation, symptoms of cholangitis can necessitate urgent cholangiography and biliary decompression. Biliary drainage is best accomplished by the transhepatic method, although successful endoscopic stent placement can also be accomplished. Parenteral antibiotics and biliary drainage should be continued until sepsis is controlled. In patients who present with jaundice but without cholangitis, cholangiography should be performed to define the anatomy. Preoperative biliary decompression in patients without cholangitis has not been demonstrated to improve outcome.

Surgical Management

The goal of operative management of bile duct stricture is the establishment of bile flow into the proximal gastrointestinal tract in a manner that prevents cholangitis, sludge or stone formation, restructure, and biliary cirrhosis. This goal is best accomplished with a tension-free anastomosis between healthy tissues. A number of surgical alternatives exist for primary repair of bile duct strictures, including end-to-end repair, Roux-en-Y hepaticojejunostomy or choledochojejunostomy, choledochoduodenostomy, and mucosal grafting. The choice of repair depends on a number of factors, including the extent and location of the strictures, the experience of the surgeon, and the timing of the repair.

Immediate Repair of Intraoperative Bile Duct Injury

In many cases, initial proper management of bile duct injury recognized at the time of cholecystectomy can avoid the development of a bile duct stricture. Unfortunately, recognition of a bile duct injury is uncommon during either open or laparoscopic cholecystectomy. If bile leakage is observed or atypical anatomy is encountered during laparoscopic cholecystectomy, early conversion to an open technique and prompt cholangiography are imperative. If a segmental or accessory duct less than 3 mm has been injured and cholangiography demonstrates segmental or subsegmental drainage of the injured ductal system, simple ligation of the injured duct is adequate. If the injured duct is 4 mm or larger, however, it is likely to drain multiple hepatic segments or the entire right or left lobe and thus requires operative repair.

If the injury involves the common hepatic duct or the common bile duct, repair should also be carried out at the time of injury. The aims of any repair should be to maintain ductal length and not to sacrifice tissue, as well as to affect a repair that will not result in postoperative bile leakage. To accomplish these goals, all repairs at the time of initial operation should involve some sort of external drainage. If the injured segment of the bile duct is short (<1 cm) and the two ends can be opposed without tension, an end-to-end anastomosis can be performed with placement of a T-tube through a separate choledochotomy either above or below the anastomosis (Fig. 62-8A). Generous mobilization of the duodenum out of the retroperitoneum (Kocher maneuver) can be useful to help approximate the injured ends of the bile duct. An end-to-end repair, however, should be avoided if the ductal injury is near the hepatic duct bifurcation. It must also be remembered that in the nontransplantation setting, the patient does not have the benefit of a lower stricture rate due to chronic immunosuppression.

Figure 62-8. All biliary anastomoses performed for the reconstruction of acute bile duct injury should have external drainage. **A:** If the injured segment of bile duct is short (<1 cm) and the two ends can be opposed without tension, an end-to-end anastomosis can be performed with placement of a T-tube through a separate choledochotomy either above or below the anastomosis. The T-tube should not be brought out directly through the anastomosis. **B:** With more proximal injuries or if the segment of injured bile duct is greater than 1 cm, an end-to-end bile duct anastomosis should be avoided and a Roux-en-Y hepaticojejunostomy should be constructed. A transanastomotic stent can be placed retrograde through the transected duct and exited to the hepatic parenchyma to allow postoperative external drainage.

5 For proximal injuries or if the injured segment of the bile duct is greater than 1 cm in length, an end-to-end bile duct anastomosis should be avoided because of the excessive tension that usually exists in these situations. In these circumstances, the distal bile duct should be oversewn, and the proximal bile duct should be debrided of injured tissue and anastomosed in an end-to-side fashion to a Roux-en-Y jejunal limb. The use of a Roux-en-Y jejunal limb is preferable to anastomosis to the duodenum because, in the latter case, an anastomotic leak results in a duodenal fistula. A transanastomotic Silastic stent can be placed retrograde through the transected duct and exiting the hepatic parenchyma (Fig. 62-8B) to allow for postoperative external drainage.

Unfortunately, most bile duct injuries during laparoscopic cholecystectomy occur in the hands of surgeons who are not experienced in performing complex biliary reconstruction. In such settings, the surgeon should consider *not* repairing the injury and not risk further worsening the situation. The biliary tree should be drained via a retrograde catheter to facilitate cholangiography, but the bile duct should not be ligated. More specifically, ligation of the proximal bile duct most often leads to stump necrosis, subsequent bile leakage and a more challenging reconstruction due to proximal migration of the injury itself.¹⁵ The subhepatic space should be well drained to control the biliary leak. Prompt transfer to a tertiary hepatobiliary center should then be made.

The long-term results of immediate repair of common bile duct injuries are uncertain. Most injuries occur away from major centers, and therefore, even the successes are unlikely to be reported in the literature. In a Swedish report, early primary repair with end-to-end anastomosis resulted in good outcomes in only 22% of patients. Anastomotic leak requiring reoperation occurred in 32% of patients, and late stricture occurred in another 37% of patients. In patients undergoing immediate repair with a biliary-enteric anastomosis, good results were seen in 54% of patients, with strictures occurring in only 12% of patients. Similar poor late results were observed in another series in which 29 of 36 patients with primary end-to-end repair had postoperative strictures within 4 years.

Elective Repair of Bile Duct Injuries and Established Strictures

Several principles are associated with successful repair of a biliary injury or stricture: exposure of healthy proximal bile ducts that provide drainage of the entire liver; preparation of a suitable segment of intestine that can be brought to the area of the stricture without tension, most frequently a Roux-en-Y jejunal limb; and creation of a direct biliary-enteric mucosal-to-mucosal anastomosis. A number of alternatives for elective repair of bile duct strictures exist. The choice of procedure is dictated by the location of the stricture, the history of previous unsuccessful attempts at repair, and the surgeon's personal preference. Simple excision of a bile duct stricture and end-to-end bile duct anastomosis or repair of the damaged duct can rarely be accomplished because of the invariable loss of duct length as a result of fibrosis associated with the injury. Similarly, anastomosis of the proximal bile duct to the duodenum as a choledochoduodenostomy is not suitable for most postcholecystectomy strictures because an adequate length of bile duct for creating a tension-free anastomosis to the duodenum usually cannot be obtained. Thus, in almost all cases, hepaticojejunostomy constructed to a Roux-en-Y limb of jejunum is the preferred procedure.

Many surgeons believe that a transanastomotic stent is helpful in almost all cases. In the early postoperative period, a stent is used to decompress the biliary tree and provide access for cholangiography. If the injury involves the common bile duct or the common hepatic duct at least 2 cm distal to the hepatic duct bifurcation, and adequate proximal bile duct mucosa can be defined, the use of long-term biliary stents is not necessary. In these situations, the preoperatively placed percutaneous transhepatic catheter or operatively placed T-tube is used to decompress the biliary-enteric anastomosis for 4 to 6 weeks after surgery. When adequate proximal bile duct is not available for a good mucosa-to-mucosa anastomosis, long-term stenting of the biliary-enteric anastomosis with a Silastic transhepatic stent is recommended. For strictures involving the hepatic duct bifurcation, both the right and left main hepatic ducts should be individually stented.

An operative technique for biliary reconstruction with transhepatic stents using the preoperatively placed percutaneous transhepatic catheters begins with dissection of the porta hepatis, which usually involves separating adhesions of the duodenum and hepatic flexure of the colon to the Glisson capsule and gallbladder fossa.¹⁶ Identification of the proximal biliary segment can be difficult and can be aided by the presence of the transhepatic biliary catheter. This is particularly true for bile duct transections that will retract high into the porta. If a primary duct stricture exists, the bile duct is then divided at the lowest extent of the stricture and dissected proximally. A segment of the strictured duct should be resected and submitted for pathologic examination. The distal duct is then oversewn, and the bile duct
